Real-Time Quantification and Display of Skin Radiation During Coronary Angiography and Intervention

Ad den Boer, BS; Pim J. de Feijter, MD; Patrick W. Serruys, MD; Jos R.T.C. Roelandt, MD

Background—Radiographically guided investigations may be associated with excessive radiation exposure, which may cause skin injuries. The purpose of this study was to develop and test a system that measures in real time the dose applied to each 1-cm² area of skin, taking into account the movement of the x-ray source and changes in the beam characteristics. The goal of such a system is to help prevent high doses that might cause skin injury.

Methods and Results—The entrance point, beam size, and dose at the skin of the patient were calculated by use of the geometrical settings of gantry, investigation table, and x-ray beam and an ionization chamber. The data are displayed graphically. Three hundred twenty-two sequential cardiac investigations in adult patients were analyzed. The mean peak entrance dose per investigation was 0.475 Gy to a mean skin area of 8.2 cm². The cumulative KERMA-area product per investigation was 52.2 Gy/cm² (25.4 to 99.2 Gy/cm²), and the mean entrance beam size at the skin was 49.2 cm². Twenty-eight percent of the patients (90/322) received a maximum dose of ≤ 1 Gy to a small skin area (≤ 6 cm²), and 13.5% of the patients (42/322) received a maximum dose of > 2 Gy.

Conclusions—Monitoring of the dose distribution at the skin will alert the operator to the development of high-dose areas; by use of other gantry settings with nonoverlapping entrance fields, different generator settings, and extra collimation, skin lesion can be avoided. (Circulation. 2001;104:1779-1784.)

Key Words: radiography ■ catheterization ■ dosage

Coronary arteriography and x-ray–guided catheter-based interventions are increasingly used. X-ray exposure may be associated with adverse effects, however, as described as early as 1897. Numerous incidents of radiation-induced skin injuries have recently been reported. Doses from the prolonged use of fluoroscopy can be very high and place the skin at risk for injury. Even though some modern x-ray equipment uses dose-saving measures, such as added filtration and dose-reducing variable-pulsed fluoroscopy, complicated procedures can still result in high-risk skin doses. It is therefore important to reduce radiation exposure as much as possible.

Newer x-ray units have an integrated ionization chamber that allows monitoring of the kinetic energy released in matter (KERMA; the absorbed dose in air)–area product, but the entrance dose and dose distribution at the skin are not indicated. Therefore, there is a need to monitor and to quantify the skin radiation dose.

We have developed a system that automatically measures and monitors the accumulated skin radiation dose and allows detection of high-dose areas in real time.

In this study, the feasibility and usefulness of this technique have been investigated by analysis of the frequency distribution of high-dose areas in consecutive patients undergoing percutaneous intracoronary procedures.
2. Gantry: Rotation and angulation in degrees and source-image distance and isocentric elevation from the floor in millimeters.

3. Collimator: X-ray beam size, horizontal and vertical, in millimeters and the KERMA-area product (KAP; sometimes called dose-area product) value in grays per square centimeters.

4. Generator: X-ray mode and fluoroscopy time (continuous or pulsed) or (digital) cine pulses.

The entrance beam location at the skin was derived from the distance from the x-ray focal spot to the patient in the transverse plane by use of the gantry rotation, focal spot position, and patient position. This distance was corrected for the gantry angulation in the longitudinal plane. The entrance beam size was calculated from the collimator beam dimensions.

The radiation dose at the skin was calculated in grays by use of the entrance beam dimensions and the KAP, measured with an ionization chamber in the collimator.

The theoretical mathematical model is not presented in this article but is available from the authors. The model is used in a monitor system developed by the Siemens Co, the prototype of which is used to retrieve the data.

**Graphical Display**

Figure 1 shows a 3D graph with the dose distribution at a 50×50-cm dorsal aspect of the skin after an interventional procedure involving the LAD, including implantation of 2 stents. This graph was generated with our prototype system during a pilot study. The graphical display of the system used for data accumulation during our study shows a skin area of 90×90 cm.

Figure 2 is a plot of skin dose depicted in a 2D plane centered over the backbone; the skin surface is virtually split at the sternum and shown laid flat. This graph is automatically displayed on the x-ray monitor after radiation of any part of the skin exceeds a level of 1 Gy. The irradiated skin area is continuously displayed and updated, even when fluoroscopy is not used. This enables the physician to change gantry settings or use extra collimating to avoid possible overlapping with previously irradiated skin parts without using radiation.

**Entrance Beam Dimensions**

Both units have automated collimation that limits the beam area to the selected field of view of the image intensifier, independent of

The graph shows the dose distribution at 50×50-cm dorsal skin part after interventional procedure from LAD, followed by implantation of 2 stents. Peak, located at right side, is due to left superior oblique projection, most radiation absorbent projection. Size of high-dose area >1 Gy was 19 cm².

![Figure 2. Graphical display of prototype system shows skin area of 90×90 cm. Graph is automatically displayed on x-ray monitor after radiation at any part of skin exceeds a level of 1 Gy. Dose report is integrated into this display. Actual irradiated skin area is marked as a square on display (even without fluoroscopy), enabling physician to avoid possible overlap with previously irradiated skin parts by extra collimating or changing gantry settings. Example shows dose distribution at skin after a procedure with 49.3 minutes of radiation time, a PTCA of LAD. Peak entrance dose (hot spot) received by skin was 1.86 Gy to an area of 5.0 cm².](image2)
changes in the source-to-image distance (SID tracking). The area of
the beam at the skin, however, does change with the source-to–
image-intensifier distance. The maximum possible beam areas
are given in Table 1.

Dose Settings of the X-Ray Equipment
The dose settings for the x-ray equipment for the pulsed fluoroscopy
mode (PFM) and the digital cine mode (DCM) during the study
period are shown in Table 2. The highest possible kilovoltage peak
(kVp) during PFM was 110 kVp, and during DCM, 125 kVp. The
frequency of PFM was adjusted to 12.5 pulses per second, and the
extra beam filter used was 0.2 mm Cu.
The scattered radiation grid had a ratio of 11 and 40 line pairs per
centimeter and a focal spot distance of 950 mm and was carbon fiber
filled and covered. The radiation measurement was performed with
an ionization chamber built into the collimator, and the KAP is
shown.

Statistics
Unless otherwise stated, numerical data are presented as median with
interquartile range.

Results

Total Radiation Dose per Investigation
The cumulative KAP per investigation was 52.2 Gy/cm²
(range 25.4 to 99.2 Gy/cm²). The mean entrance beam size at
the skin was 49.2 cm², giving an absolute value of 1.06 Gy
(Figure 3).

Radiation Time
The mean fluoroscopy time was 17.8 seconds (range 8.8 to
33.1 seconds), with pulsed fluoroscopy of 12.5 pulses per
second. The mean DCM time was 97.9 seconds (range 69.4 to
151.1 seconds), with a frequency of 12.5 frames per second.

Irradiated Skin Surface
The radiation-exposed skin area in 95% of all investigations
was restricted to a size of 50×50 cm, including the irradiated
area at the groin for catheter introduction and left lateral
gantry positioning. This is shown in Figure 1. In the remaining
5% of the cases, the exposed skin area could be visualized
by showing a 90×90-cm area.

Peak Entrance Dose
The distribution of peak entrance skin doses to the patients in
our series is shown in Figure 4. The mean value was 0.475
Gy, with a mean area of 8.2 cm² exposed. Dose values > 1 Gy
occurred in the majority of the patients (52%), whereas parts
receiving a dose > 4 Gy occurred in only 1.2%. Because our
system alerted us in real time when a high-dose area was
developing, we were able to avoid excessive dose to that area
by changing the gantry settings. It was not necessary to
interrupt any procedure as a result of a high-dose “hot spot.”

Correlation Between the Measured KAP, Patient
Obesity, and Fluoroscopy Time
The correlation between the measured KAP and the obesity
of the patient, the Quetelet index (kg/m²), was low (R = 0.15).
Higher doses were correlated with gantry projections that
required penetration of thick, highly absorbent body masses.
There was a strong relationship between the KAP and
fluoroscopy time (R = 0.78) (Figure 5).

Correlation Between Measured KAP and Peak
Entrance Dose
There was a high correlation between measured KAP and
peak entrance dose (R = 0.89) (Figure 6). We also compared
the correlation between KAP and the high-dose areas in the
134 diagnostic and the 188 interventional procedures. The
correlation between the interventional procedures (R = 0.90)
was higher than the correlation between diagnostic proce-
dures (R = 0.35) because of more frequent changing of gantry
settings and less overlapping of entrance fields in diagnostic
cases.

![Figure 3. KAP measured in 322 patients. Mean value was 52.19 Gy/cm² (range 25.4 to 99.2 Gy/cm²). Mean size of entrance beam was 49.2 cm².](image-url)
Validation of the Measured KAP
The ionization chamber readings were verified regularly with other measuring devices; the accuracy of the KAP readings was within a 5% range. The values that appear on the monitor reflect the free-in-air KERMA, measured in grays. The dose to the tissue is actually 30% to 40% greater than the value displayed during monitoring, because of backscattered radiation and the KERMA-to–tissue-dose conversion factor.

Discussion
Skin injury as a result of radiation exposure was reported as early as 1897. The number of radiologically guided interventions is increasing, as well as the amount of radiation used per procedure. Recent publications show an increasing number of skin injuries during cardiac, abdominal, and neurological interventions. High entrance-dose values cannot be avoided in complex investigations, because they often require long exposure times.

Our method allows for skin dose management and makes it possible to keep the dose at a certain skin area as low as reasonable for the procedure. This is important because many patients have more than one procedure, and skin dose accumulates.

It should be kept in mind that a high dose may produce unacceptable skin damage and should be avoided (Table 3). Real-time dose monitoring can prevent these adverse effects because it allows selection of other x-ray techniques, such as extra beam filtering, selection of lower frame rates, and if available, documenting of low-dose fluoroscopic runs during the procedure. Extra beam collimation is not often used but is a highly effective way to decrease both patient and operator radiation exposure without loss in image quality.

Finally, the use of other gantry settings allows distribution of the radiation dose over different skin areas and prevents development of a high dose. In our study, only 1.2% of the patients received a dose >4 Gy at some parts of the skin. It should be noted, however, that when equipment without dose-saving measures is used, levels are much higher (up to 7 times).

Limitations
The monitoring system used in this study assumed a patient with a thorax circumference of 90 cm. Obviously, this does not apply to all patient sizes.

Figure 4. Peak entrance dose measured in 322 patients; mean value was 0.475 Gy. Mean size of high-dose area was 8.2 cm².

Figure 5. Correlation between measured KAP and fluoroscopy time for complete patient group: $R=0.78$, $x=-75.19$, $y=327.83$. With extreme values taken out, fluoroscopy times >100 minutes showed $R=0.70$, $x=537.42$, $y=296.15$. Mean KAP was 52.19; mean fluoroscopy time used was 17.8 minutes.
not apply to all patients, and ideally, a monitoring system should be tailored to the size of the patient. The actual size and location of irradiated skin parts may vary from one individual to another; future refinements to model the dimensions of individual patients more accurately would improve the accuracy of the skin dose distribution.

Clinical Recommendations

Our data show that the likelihood of high-dose areas may occur in the following circumstances: fluoroscopy time >60 minutes; gantry positioning unchanged throughout the procedure; and the irradiation occurring through a highly attenuating (eg, bone), thick body mass, requiring a high radiation quality during fluoroscopy and cinematography (>110 kVp). High-dose areas most likely occur when the left superior oblique projection is used.
