Accumulation of Foam Cells in Liver X Receptor–Deficient Mice

Gertrud U. Schuster, PhD*; Paolo Parini, MD, PhD*; Ling Wang, MD, PhD; Siegfried Alberti, PhD; Knut R. Steffensen, MSc; Göran K. Hansson, MD, PhD; Bo Angelin, MD, PhD; Jan-Åke Gustafsson, MD, PhD

Background—The nature of some of the target genes for liver X receptors (LXRs)-α and -β, such as sterol regulatory element binding protein-1 and ATP-binding cassette transporter proteins, suggests a pivotal role of these nuclear receptors in the regulation of fatty acid and cholesterol homeostasis. The present study aimed to elucidate the physiological relevance of both LXRs with regard to lipid metabolism and macrophage cholesterol efflux.

Methods and Results—Mice depleted for LXRα, LXRβ, or both were fed low-fat rodent chow for 18 months before investigations. The combined deficiency of LXRα and LXRβ was linked to impaired triglyceride metabolism, increased LDL and reduced HDL cholesterol levels, and cholesterol accumulation in macrophages (foam cells) of the spleen, lung, and arterial wall.

Conclusions—Our data demonstrate the physiological importance of both LXRs in lipid metabolism and strongly indicate that both LXRs have a protective role against the development of atherosclerosis. (Circulation. 2002;106:1147-1153.)

Key Words: receptors, liver X • atherosclerosis • lipoproteins • fatty acids • cholesterol

During the past few years, the liver X receptors (LXRα and LXRβ), for which different oxysterols serve as ligands, have been recognized as important regulators of lipid and lipoprotein metabolism by identification of various target genes.1 In vitro, both LXRα and LXRβ regulate the transcription of cholesterol 7α-hydroxylase (Cyp7a),1 the rate-limiting enzyme in bile acid biosynthesis. In response to dietary cholesterol, however, only LXRα−/− but not LXRβ−/− mice fail to upregulate the hepatic conversion of cholesterol into bile acids.1 This was associated with increased total cholesterol, LDL cholesterol, and 24- and 27-hydroxycholesterol levels in the serum.2

By regulating the expression of the sterol regulatory element binding protein-1 (SREBP-1) and acetyl CoA decarboxylase, fatty acid synthase, and lipoprotein lipase, LXRs influence metabolism of fatty acids, triglycerides, and triglyceride-rich lipoproteins.3,4 In addition, LXRs promote the transcription of the cholesterol ester transfer protein and apolipoprotein E (apoE).1 Furthermore, in vitro studies have shown that LXRα and LXRβ regulate several ATP-binding cassette transporter proteins (ABCs). In the enterocytes, LXRs activate the transcription of ABCA1, ABCG5, and ABCG8 and thus regulate intestinal cholesterol absorption. In macrophages, LXRs affect the cholesterol efflux into HDLs, by regulating the expression of ABCA1 and ABCG1.1 As the formation of foam cells by cholesterol accumulation in arterial wall macrophages is a crucial first step in atherogenesis,5 an antiatherogenic effect of LXRs may be postulated.1

The majority of data on the role of LXRs in cholesterol and triglyceride metabolism, however, has been generated either in vitro or under nonphysiological conditions, such as cholesterol challenge in mice. Neither LXRα−/− nor LXRβ−/− mice showed any morphological alterations or any disturbances in cholesterol metabolism when fed standard rodent chow.2 Thus, the physiological relevance of LXRs for lipid homeostasis and atherogenesis remains to be convincingly demonstrated in vivo. To establish whether LXRs play such a physiological role, mice depleted for LXRα, LXRβ, or both were fed a low-fat rodent chow and followed for 18 months. In particular, our investigation focused on cholesterol efflux from macrophages and on hepatic lipid and serum lipoprotein metabolism. For the first time, we were able to show that combined deficiency of LXRα and LXRβ leads to cholesterol accumulation in macrophages (foam cells) of spleen, lung, and arterial wall in aging animals fed a normal diet. This was associated with increased LDL and reduced HDL cholesterol, despite normal total cholesterol levels in the serum. Our data substantiate the view that LXRs have a protective role in atherogenesis.

Methods

Animals

LXRα−/−, LXRβ−/−, and wild-type mice were generated in our laboratory as described previously.2 LXRα−/−β−/− mice were ob-
tained by several mating steps, beginning with LXRα<sup>−/−</sup> and cre-
transgenic LXRβ<sup>−/−</sup> founder animals. All mice used in our study
(LXRα<sup>−/−</sup>, LXRβ<sup>−/−</sup>, LXRα<sup>−/−</sup>β<sup>−/−</sup> mice and wild-type controls) had a
similar mixed genetic background based on 129/Sv and C57Bl/6 strains.
Mice with pure Sv129 background were backcrossed in C57BL/6 mice
for 2 generations, unless otherwise stated. Animals were housed with
a regular 12-hour/12-hour light/dark cycle and fed a low-fat standard
rodent chow diet (R36 Lactamin AB) ad libitum. Experiments were
approved by the local ethics committee for animal experiments.

Chemical Analysis of Serum and Tissue

Blood was drawn by cardiac puncture under light methoxyflurane
anesthesia before tissues were collected. Total cholesterol and
triglycerides were determined individually using a commercially
available kits (Roche Molecular Biochemicals). Values were used
to the respective glycerol content. Size-fractionation of lipoproteins
was performed on 10 μL of pooled sera from each group, using a
micro fast protein liquid chromatography column (FPLC; 30×0.32
cm Superose 6B, Amersham Pharmacia Biotech AB) at a flow rate
of 0.5 mL/min, as previously described<sup>2</sup> FPLC separation of sera
from individual animals was performed to quantitate cholesterol and
triglyceride content in the different lipoprotein fractions, calculated
as described<sup>6</sup> (EZ Chrom, Scientific Software Inc). Values were used
to calculate the LDL/HDL ratio; individual data were expressed as a
percentage of the mean of wild-type mice before statistical analysis.
Lipids in liver, spleen, and lung were extracted according to Folch et
al.<sup>7</sup> Total cholesterol and triglycerides were analyzed using commer-
cially available kits (Roche Molecular Biochemicals).

Histology and Immunohistochemistry

Lungs, spleens, and livers were fixed in 4% formaldehyde solution,
(Sigma) embedded in paraffin, and stained with hematoxylin and
eosin. For cryosections, spleen, lung, liver, heart, and proximal aorta
were snap-frozen in Tissue-Tek (Sakura Finetek Europe BV). Lipid
deposits were visualized by staining with hematoxylin and oil red O
on 10-μm cryosections as previously described.<sup>8</sup> Macrophages were
detected using the monoclonal antibody against CD11b (Mac-1;
PharMingen), followed by biotinylated anti-mouse IgG, horseradish
peroxidase–labeled avidin, and diaminobenzidine/H<sub>2</sub>O<sub>2</sub> (Vector Lab-
oratory). Aortic lipid infiltration was quantified by measuring the oil
red O-stained surface area inside the external elastic lamina (ie,
intima and media) in cross-sections at 0-, 200-, and 400-μm
distances from the aortic valves. Measurements were made with a
computer program written in Quips language, by use of a Leica
DMRB microscope operating at 200× magnification linked with a
Leica Q500IW image analysis system.

Northern Blot Analysis

Northern blot analysis was performed on 2 to 5 μg hepatic poly
(A+)-RNA using 32P-labeled cDNA probes as described.<sup>2</sup> Signals on
Northern blot filters were quantitated by use of a PhosphorImage
Analyzer (Fuji Sverige AB) and normalized according to GAPDH
mRNA expression; data represent results from 4 to 9 individual
animals, from ≥2 independent determinations. cDNA probes were
generated by reverse transcription–polymerase chain reaction from
mouse liver as previously described<sup>2</sup> or by following oligonucleo-
tides: ABCA1, 5′-CTGATGAGGTGGGATAGC-3′ and 5′-AGCAGAGATGGACAGATGG-3′.

Statistics

Data are presented as mean±SEM. The significance of differences
between groups was tested by 1-way ANOVA, followed by post-hoc
comparisons according to Dunnett’s tests, by planned comparisons
or by Tukey’s honestly significant difference test (Statistica soft-
ware, Stat Soft).

Results

Serum Lipids and Lipoprotein Pattern

Analysis of total cholesterol in serum showed no differences
between wild-type controls, LXRα<sup>−/−</sup>, LXRβ<sup>−/−</sup>, or LXRα<sup>−/−</sup>β<sup>−/−</sup>
mice (Figure 1A), in line with previously published data on 12- to
16-week-old LXR single-mutant mice fed standard rodent chow.<sup>2</sup>
In this study, however, pronounced differences in cholesterol
content of the different lipoprotein classes were observed between
mouse lines after separation by FPLC (Figure 1B). LXRα<sup>−/−</sup> mice
tended to have an increase in LDL (P<0.005; P<NS) and a
decrease in HDL cholesterol (−17±7.4%; P<NS) compared with
that of wild-type controls. No distinct changes were observed in
LXRβ<sup>−/−</sup> mice. Young LXR single-mutant mice had no differences in
lipoprotein distribution.<sup>1</sup> In double-mutant mice, cholesterol
content was increased by 83±16% (P<0.05) in LDL particles and
tended to be decreased (26±2.6%; P<NS) in HDL particles. These
changes in lipoprotein cholesterol distribution resulted in 86±45% (P<0.05) and 150±26% (P<0.001) increases of the LDL/HDL cholesterol ratio in $LXR\alpha^{-/-}$ and double-mutant mice, respectively.

Compared with wild-type controls, serum triglycerides were reduced by 70% in double-mutant mice, whereas no significant differences were observed in $LXR\alpha^{-/-}$ or $LXR\beta^{-/-}$ mice (Figure 1C; P<0.001). VLDL triglycerides were reduced by 79±4.3% (P<0.01) and LDL triglycerides by 63±6.9% (P<0.01) in $LXR\alpha^{-/-}\beta^{-/-}$ mice (Figure 1D). No distinct changes were observed in $LXR\alpha^{-/-}$ mice, whereas there was a trend toward a reduction of VLDL and LDL triglycerides in $LXR\beta^{-/-}$ mice (~38±12%, P=NS; and −20±12%, P=NS; respectively).

The changes in lipid composition of lipoproteins prompted an analysis of the electrophoretic mobility of lipoproteins. No differences in mobility were observed among the groups (data not shown).

### Lipid Content in Tissues

In the spleen, analysis of cholesterol content revealed no changes in $LXR\alpha^{-/-}$ or $LXR\beta^{-/-}$ mice. However, there was a 2-fold increase (P<0.001) in total cholesterol in the spleen from $LXR\alpha^{-/-}\beta^{-/-}$ mice (Figure 2A). Triglyceride content tended to decrease in spleens from $LXR\beta^{-/-}$ and $LXR\alpha^{-/-}\beta^{-/-}$ mice (Figure 2A). No changes in triglyceride levels were observed in $LXR\alpha^{-/-}$ spleens. In lungs, a 3-fold increase (P<0.001) in total cholesterol was observed in double-mutant mice (Figure 2B). No changes in $LXR\alpha^{-/-}$ or $LXR\beta^{-/-}$ mice were found with regard to cholesterol or triglyceride levels, but a 70% reduction (P<0.05) of triglycerides was observed in lungs from $LXR\alpha^{-/-}\beta^{-/-}$ mice (Figure 2B). In livers, an increase in cholesterol (3-fold; P<0.001) was found in $LXR\alpha^{-/-}\beta^{-/-}$ mice (Figure 2C) but not in 16-week-old $LXR\alpha^{-/-}$ or $LXR\beta^{-/-}$ mice. Furthermore, hepatic triglycerides dramatically decreased (by 90%) in double-mutant mice (Figure 2C; P<0.001). In $LXR\beta^{-/-}$ mice, triglycerides were reduced by 80% (P<0.05), whereas only a tendency to a decrease was observed in $LXR\alpha^{-/-}$ mice.

### Tissue Morphology

Histological analysis revealed accumulation of foam cells in the spleens of $LXR\alpha^{-/-}\beta^{-/-}$ mice (Figure 3A). In contrast, foam cells were not seen in $LXR\alpha^{-/-}$ or $LXR\beta^{-/-}$ mice (Figure 3C and 3D). To characterize these cells further, cryosections were prepared and stained for lipids with oil red O (Figure 3E and 3F). Cells from $LXR\alpha^{-/-}\beta^{-/-}$ mice (Figure 3E) were filled with lipid droplets, and staining of parallel sections indicated that they expressed CD11b and were thus of macrophage origin (Figure 3G). Large foam cells and coalescent lipid accumulations were found in the center of the white pulp, whereas smaller foam cells were scattered throughout the red pulp.

Substantial foam cell accumulations were also observed in the lungs of $LXR\alpha^{-/-}\beta^{-/-}$ mice, particularly in the alveolar sacks, surrounded by normal epithelial cells (Figure 4A). Oil red O staining confirmed that foam cells were filled with coalescent lipid droplets (Figure 4B). The lungs from $LXR\alpha^{-/-}$ and $LXR\beta^{-/-}$ mice were normal (Figure 4C and 4D).

None of the mice showed accumulation of foam cells in the livers, irrespective of their genotype (Figure 5). Oil red O staining of hepatic cryosections revealed a less pronounced intracellular lipid accumulation in $LXR\alpha^{-/-}\beta^{-/-}$ mice compared with wild-type controls (Figure 5E and 5F). Macrophages could not be detected in the livers from $LXR\alpha^{-/-}\beta^{-/-}$ mice as judged by CD11b staining of parallel sections (Figure 5G and 5H).

Cryosections of the aortic root of LXR knockout mice showed lipid accumulation after staining with oil red O (Figure 6). Occasional lipid deposits were also observed in the aortic root from mice deficient in either LXRα or LXRβ (Figure 6C and 6D), but the larger infiltrates were confined to mice deficient in both LXRα and LXRβ (Figure 6A and 6E). Wild-type mice did not exhibit any aortic lipid accumulations (Figure 6B). In the aortas of $LXR\alpha^{-/-}\beta^{-/-}$ mice, lipids were present both extracellularly in the subendothelial region and in lipid-laden foam cells (Figure 6E). The latter cells were identified as CD11b+ by immunohistochemical staining of parallel sections (data not shown).

To quantitate lipid infiltration, the oil red O–stained area was measured in aortic cross-sections of $LXR\alpha^{-/-}$, $LXR\beta^{-/-}$, $LXR\alpha^{-/-}\beta^{-/-}$, and wild-type mice (Table). The aortas in $LXR\alpha^{-/-}$ and $LXR\beta^{-/-}$ mice exhibited a 3.3-fold and a 5-fold increase, respectively, in lipid infiltrated area compared with those of wild-type mice (P=NS). In the absence of both LXRs, the lipid content of the intima-media cross-sectional...
area was increased 27-fold (P<0.05; both versus wild-type and single-mutant mice).

**Hepatic mRNA Levels and Lipoprotein Receptor Expression**

We then examined the relative mRNA levels of several genes regulating cholesterol and lipid metabolism in the livers from LXRα/−/−, LXRβ/−/−, LXRα/−/−β/−/−, and wild-type mice (Figure 7). The mRNA levels of ABCA1 were significantly reduced in both LXRβ/−/− and LXRα/−/−β/−/− mice (to 42% and 26% of controls), whereas no significant reduction was observed for ABCG1. Furthermore, LDL receptor mRNA expression was increased 2-fold in LXRα/−/−β/−/− mice, whereas SREBP-2 and apoE expression was unchanged. Expression of SREBP-1 increased 2-fold in LXRβ/−/− mice but decreased to 35% in LXRα/−/−β/−/− mice (Figure 7).

Hepatic LDL receptor protein, assayed by ligand blotting, was similar in all groups of animals (data not shown).

**Discussion**

Several new and important conclusions can be drawn from the present study. For the first time, we show that combined deficiency of both LXRs results in foam cell accumulation in several organs, including the aorta. Interestingly, these changes were observed in animals on a normal diet, displaying distinct abnormalities of circulating lipoproteins. In general, mice are resistant to atherosclerosis, unless they are challenged with a specific high-fat diet or carry deletions of key genes in cholesterol metabolism, such as apoE or the LDL receptor, leading to drastic elevations of cholesterol-rich plasma lipoproteins. Despite the fact that the animals were followed for 18 months, the lesions in the aorta of LXRα/−/−β/−/− mice only consisted of foam cell accumulation and did not progress into raised lesions or advanced atheromas. Therefore, LXRs are important for macrophage cholesterol efflux, but defects in the macrophages or elsewhere based on the deletion of both LXRs do not cause advanced atherosclerosis. Cholesterol efflux from macrophages is a complex process relying on ABCA1, ABCG1, apoE, SR-B1, 27-hydroxylation of cholesterol, and aqueous diffusion. Among the target...
genes for the LXRs are ABCA1, ABCG1, and apoE. The ABC proteins have recently been shown to be important for apoAI-mediated phospholipid and cholesterol efflux from different cell types, particularly macrophages.2 LXRs regulate the transcriptional activity of the ABCA1 and ABCG1 genes and thus promote the oxysterol-induced cholesterol efflux to HDL.3 Similar to what is observed for the ABCs, LXRs increase the basal gene expression of apoE in macrophages in response to oxysterols.1 These observations lead to the hypothesis that formation of cholesterol-loaded macrophages owing to LXR deficiency results from the inability to upregulate the ABC- and apoE-mediated cholesterol efflux from macrophages, the initial step of reverse cholesterol transport. An increased 27-hydroxycholesterol/cholesterol ratio is also present in LXR deficient mice (G.U. Schuster, unpublished observation, 2002), probably in line with a higher availability of substrate for sterol 27 hydroxylase, secondary to the impaired cholesterol efflux from macrophages. In LXRα/−β−/− mice, foam cells accumulate in the spleen, lungs, and aorta. Except for the aorta, a similar phenotype is also seen in ABA1−/− mice,12–16 an animal model resembling the human disorder Tangier disease, which is characterized by low HDL cholesterol levels and cholesterol loading of reticuloendothelial cells.17 Although data on the degree of foam cell accumulation in ABA1−/− mice are somewhat conflicting,12–16 LXRα/−β−/− mice seem to display more foam cells in the peripheral organs compared with those in ABA1−/− mice. This would be in concert with the view that LXR has a more general and thus more important role than ABCA1 in determining the degree of cholesterol accumulation in macrophages.

Foam cells were not observed in livers from LXRα/−β−/− mice, but a significant increase in cholesterol accumulation occurred within the hepatocytes. It is of interest to note that the expression of ABCA1 was reduced significantly in the livers of these animals. Recently, it has been shown that ABA1−/− mice have an enhanced cholesterol synthesis in peripheral organs, like spleen and adrenals, but not in the liver.12–16 Thus, disruption of both LXRs does not result in an identical phenotype to that observed in ABA1−/− mice. Surprisingly, LXRα/−β−/− mice, in contrast to ABA1−/− mice, had only minor reduction in HDL cholesterol. Hence, it
seems that in \( LXR^\alpha^\beta^- \) mice, HDL synthesis is not dependent on ABCA1 gene expression in the liver.

In addition to the expected finding of increased cholesterol content in the spleen, liver, and lungs of LXR double-mutant mice, triglycerides were drastically reduced in these tissues, combined with low serum triglycerides. These findings could be explained by the regulation of expression of SREBP-1, acetyl CoA carboxylase, and fatty acid synthase by LXR in the liver. Indeed, an LXR-dependent increase in triglyceride levels in vivo has recently been described. The observed 2-fold induction of hepatic SREBP-1 expression, together with reduced liver triglyceride levels, in \( LXR^\beta^- \) mice suggests that in vivo, LXR might regulate triglyceride metabolism differently from LXR and independently of SREBP-1. In association with the subtle decrease in HDL cholesterol, analysis of lipoproteins revealed a significant increase in LDL cholesterol in \( LXR^\alpha^\beta^- \) mice. Such a pattern, although of a greater magnitude, has also been described in combined \( LDL-receptor^{-} \) and \( APOBEC-1^{-} \) mice. However, in that mouse model, serum triglyceride levels were increased 2-fold, whereas a 70% reduction in serum triglycerides was observed in \( LXR^\alpha^\beta^- \) mice, presumably owing to an impaired fatty acid and triglyceride metabolism. Triglycerides were decreased in the fractions corresponding to VLDL and LDL particles in \( LXR^\alpha^- \) mice. Low triglyceride levels in lipoproteins of VLDL/LDL size are also seen in apoE-deficient mice. In such animals, however, these lipoproteins mainly consist of chylomicron remnants, whereas in the LXR double-mutant mice there was no accumulation of remnants. Another clear difference between \( apoE^+ \) mice and LXR double-mutant mice is in hepatic triglyceride levels. \( apoE^+ \) mice accumulate triglycerides in the liver, whereas in the LXR double-mutant mice there was lower hepatic triglycerides. Disruption of the apoE gene results in a clear reduction of VLDL secretion. Similar to what is observed in macrophages from LXR double-mutant mice, the basal expression of apoE in the liver was not altered. Considering triglyceride availability as a rate-limiting

factor for hepatic VLDL production, we hypothesize that VLDL secretion from the liver is reduced in LXR double-mutant mice, independently of apoE.22

In conclusion, we have shown that disruption of LXRα and LXRβ leads to foam cell formation in ageing mice, even on a normal diet, and to impaired triglyceride metabolism. We hypothesize that the cholesterol accumulation in macrophages is owing to the combination of an enhanced cholesterol deposition—secondary to increased LDL cholesterol—and a failure to adequately increase the ABC- and apoE-mediated cholesterol efflux from these cells. The LXR double-knockout mouse should provide a useful animal model to study the early interaction between lipoproteins and the arterial wall.
