Background—Obesity is an escalating pandemic in the United States, and its association with coronary heart disease is well understood. Several studies have found positive associations between body mass index (BMI) and stroke in men, but the association with stroke and its subtypes is less clear in women.

Methods and Results—This was a prospective cohort study among 39,053 women participating in the Women’s Health Study. BMI was measured as self-reported weight (in kilograms) divided by height (in meters) squared. Incident stroke was self-reported and confirmed by medical record review. We used the Cox proportional hazards model to evaluate the association between BMI and stroke. After a mean follow-up of 10 years, a total of 432 strokes (347 ischemic, 81 hemorrhagic, and 4 undefined) occurred. We found a statistically significant trend for increased risk of total and ischemic stroke across 7 BMI categories. With World Health Organization criteria, women who were obese (BMI \(\geq 30\) kg/m\(^2\)) had hazard ratios of 1.50 (95% CI 1.16 to 1.94) for total stroke, 1.72 (95% CI 1.30 to 2.28) for ischemic stroke, and 0.82 (95% CI 0.43 to 1.58) for hemorrhagic stroke compared with women with BMI <25 kg/m\(^2\). Additional control for history of hypertension, diabetes, and elevated cholesterol substantially attenuated the hazard ratios for total and ischemic stroke. There was no effect modification for age, exercise, or smoking.

Conclusions—In this large prospective cohort study among women, BMI was a strong risk factor for total and ischemic stroke but not for hemorrhagic stroke. The association was highly mediated by hypertension, diabetes, and elevated cholesterol. (Circulation. 2005;111:1992-1998.)

Key Words: obesity ■ stroke ■ epidemiology ■ women
baseline in beginning of 1993 and without a history of cardiovascular disease, cancer, or other major illnesses were randomly assigned to 1 of 4 treatment groups: active aspirin (100 mg on alternate days), active vitamin E (600 IU on alternate days), both active agents, or both placebos. Baseline information was self-reported and was collected by a mailed questionnaire that asked about a large number of cardiovascular risk factors and lifestyle variables. Twice in the first year and annually thereafter, participants were sent follow-up questionnaires that asked about study compliance, study outcomes (including stroke), personal characteristics, medical history, and health habits during the study period. For the present analysis, we included follow-up information from the time of randomization through March 31, 2004. As of this date, follow-up was 96% complete. The Institutional Review Board of the Brigham and Women’s Hospital approved the study.

Assessment of BMI

Participants reported their height and weight on the baseline questionnaire. On the 24-, 36-, 60-, 72- and 108-month questionnaires, participants were asked again to report their weight, and on the 72- and 108-month questionnaires, they were asked to report their height again. BMI was calculated as self-reported weight in kilograms divided by height in meters squared (kg/m²). We used the baseline height information to calculate BMI for all but the 72- and 108-month time points. We categorized BMI into a priori categories of height information to calculate BMI for all but the 72- and 108-month time points. We categorized BMI into a priori categories of

World Health Organization (WHO) categories of

34.9, and

20.0, 20.0 to 22.9, 23.0 to 24.9, 25.0 to 26.9, 27.0 to 29.9, 30.0 to

month time points. We categorized BMI into a priori categories of

nonfatal stroke was defined as a focal neurological deficit of sudden onset and vascular mechanism that lasted ≥ 24 hours. Cases of fatal stroke were documented by evidence of a cerebrovascular mechanism obtained from all available sources, including death certificates and hospital records. Stroke was classified according to the criteria established by the National Survey of Stroke as ischemic stroke, hemorrhagic stroke, and unknown subtype. The interobserver agreement of the classification of stroke and its major subtypes in the WHS was excellent.

Statistical Analysis

Of the 39 876 randomized participants, we excluded 820 women due to incomplete follow-up information from the time of randomization. The Institutional Review Board of the Brigham and Women’s Hospital approved the study.

Assessment of BMI

Participants reported their height and weight on the baseline questionnaire. On the 24-, 36-, 60-, 72- and 108-month questionnaires, participants were asked again to report their weight, and on the 72- and 108-month questionnaires, they were asked to report their height again. BMI was calculated as self-reported weight in kilograms divided by height in meters squared (kg/m²). We used the baseline height information to calculate BMI for all but the 72- and 108-month time points. We categorized BMI into a priori categories of

World Health Organization (WHO) categories of

20.0, and

25 (normal weight), 25 to 29.9 (overweight), and ≥30 kg/m² (obese), as well as a continuous term.

Ascertainment of Stroke

Participants who reported a stroke on a follow-up questionnaire were asked for permission to review their medical records. A diagnosis of stroke was confirmed only after review of the medical records by an End Points Committee of physicians that included a neurologist. A nonfatal stroke was defined as a focal neurological deficit of sudden onset and vascular mechanism that lasted ≥24 hours. Cases of fatal stroke were documented by evidence of a cerebrovascular mechanism obtained from all available sources, including death certificates and hospital records. Stroke was classified according to the criteria established by the National Survey of Stroke as ischemic stroke, hemorrhagic stroke, and unknown subtype. The interobserver agreement of the classification of stroke and its major subtypes in the WHS was excellent.

Results

After a mean of 10 years of follow-up (384 345 person-years), a total of 432 strokes occurred among the 39 053 participants, including 347 ischemic, 81 hemorrhagic, and 4 undefined strokes. The mean BMI was 26.0 kg/m² (± 5.1 SD), with 19 841 women (50.8%) reporting BMI values of ≤ 25.0 kg/m², 12 081 (30.9%) reporting values between 25.0 and 29.9 kg/m², and 7131 (18.3%) reporting BMI ≥30 kg/m². The association between BMI WHO categories and baseline characteristics is summarized in Table 1. Women who reported BMI values of 30 kg/m² or higher more frequently reported a history of hypertension, elevated cholesterol, and diabetes. In addition, they smoked fewer cigarettes, drank less alcohol, exercised less, and reported less postmenopausal hormone use.

Table 2 presents the association between BMI in 7 categories and risk of total, ischemic, and hemorrhagic stroke. After adjustment for age, smoking, alcohol consumption, exercise, and postmenopausal hormone use, there was a significant trend of an increased risk for total and ischemic stroke across BMI categories (both P for trend <0.01). The risk was noticeably increased for women with BMI values ≥27 kg/m². Compared with participants with BMI <20 kg/m², women with BMI ≥35 kg/m² had an HR of 2.05 (95% CI 1.18 to 3.55) for total stroke and 2.81 (95% CI 1.45 to 5.43) for ischemic stroke. The risk of total and ischemic stroke was attenuated substantially when models were also controlled for history of hypertension. Additional control for history of diabetes and elevated cholesterol further attenuated the HRs to 1.19 (95% CI 0.68 to 2.10) for total stroke and 1.54 (95% CI 0.79 to 3.02) for ischemic stroke. In contrast to the positive association between BMI and total and ischemic stroke, there was no consistent association between BMI and hemorrhagic stroke. There was, however, a suggestion that women in the leanest BMI category (<20 kg/m²) in fact had an increased risk of hemorrhagic stroke compared with women with BMI 20.0 to 22.9 kg/m² (Figure 1), although this was not statistically significant (HR 2.09, 95% CI 0.89 to
This pattern was different from that seen for ischemic stroke. When we used WHO categories for BMI, women in the obese category (≥30 kg/m²) had multivariable-adjusted (model 1) HRs of 1.50 (95% CI 1.16 to 1.94) for total stroke, 1.72 (95% CI 1.30 to 2.28) for ischemic stroke, and 0.82 (95% CI 0.43 to 1.58) for hemorrhagic stroke compared with women with BMI <25 kg/m². After we additionally con-

*P for trend across categories.
†Adjusted for age, smoking status, exercise, alcohol consumption, and postmenopausal hormone use.
‡Adjusted for all variables in model 1 plus history of hypertension.
§Adjusted for all variables in model 2 plus history of diabetes and elevated cholesterol.
trolled for history of hypertension, diabetes, and elevated cholesterol, the risks of total and ischemic stroke were attenuated to 1.04 (95% CI 0.80 to 1.37) for total stroke and 1.15 (95% CI 0.85 to 1.55) for ischemic stroke.

When we evaluated BMI as a continuous variable, a 1-unit increase in BMI was associated with a 4% increase in total stroke (multivariable [model 1]-adjusted HR 1.04, 95% CI 1.02 to 1.06) and a 5% increase for ischemic stroke (HR 1.05, 95% CI 1.03 to 1.07) but had no association with hemorrhagic stroke (HR 0.99, 95% CI 0.94 to 1.04). These relative risks for total and ischemic stroke were also attenuated after we controlled for history of hypertension, diabetes, and elevated cholesterol: 1.01 (95% CI 0.99 to 1.03) for total stroke and 1.02 (95% CI 0.99 to 1.04) for ischemic stroke.

When we updated the information on BMI over the course of follow-up, the results were similar in direction compared with the association between baseline BMI and risk of stroke and stroke subtypes. After adjustment for potential confounders (model 1), women with BMI values ≥35 kg/m² had HRs of 1.66 (95% CI 1.01 to 2.71) for total stroke, 1.89 (95% CI 1.09 to 3.26) for ischemic stroke, and 0.79 (95% CI 0.23 to 2.65) for hemorrhagic stroke. As before, the HRs for total and ischemic stroke were attenuated when we additionally controlled for history of hypertension, diabetes, and elevated cholesterol, with HRs of 1.02 (95% CI 0.62 to 1.69) for total stroke and 1.10 (95% CI 0.63 to 1.94) for ischemic stroke.

The association between BMI and total, ischemic, or hemorrhagic stroke was not statistically significantly modified by age (<60 versus ≥60 years; \(P\) for all stroke types ≥0.09). The association between BMI categories according to smoking status is summarized in Figure 2. There was a progressive increase in risk with higher BMI among never-smokers and past smokers. Women who were current cigarette smokers had increased risk irrespective of BMI. Overall, there was no statistically significant effect modification of the association between BMI and ischemic stroke by smoking status (\(P=0.62\)). There was also no significant effect modification by smoking status with regard to hemorrhagic stroke.

The association between BMI WHO categories according to exercise categories is presented in Table 3. Compared with women with BMI <25 kg/m², there was an excess risk of total and ischemic stroke for BMI 30 kg/m² or higher whether or not the women exercised. The HRs were somewhat stronger in those who exercised less, but there was no statistically significant effect modification (\(P=0.39\) for all stroke types).

**Discussion**

In this large prospective cohort study of >39 000 apparently healthy women, BMI was strongly associated with total and ischemic stroke but not with hemorrhagic stroke. We found a statistically significant trend across BMI categories for total and ischemic stroke and found significant increased risks for ischemic stroke beginning with BMI values ≥27.0 kg/m² that steadily increased with higher BMI. Women with BMI ≥35 kg/m² had a 2-fold increase in the risk of total stroke and an almost 3-fold increase in the risk of ischemic stroke compared with women with BMI <20 kg/m². When WHO criteria were used, women who were obese (BMI ≥30 kg/m²) had a 1.5-fold increase in the risk of total stroke and a 1.7-fold increase in the risk of ischemic stroke compared with women with BMI <25 kg/m². The association between BMI and total and ischemic stroke was strongly mediated by history of hypertension, diabetes, and elevated cholesterol. The association between BMI and stroke was not modified by age, smoking status, or exercise.

Over the last 2 decades, the association between obesity and stroke among women has been inconsistent, with some studies showing a positive association,11,12,28–30 and others showing no association.31–33 Data from the Nurses’ Health Study showed similar associations as in the present study and found a >2-fold increase in the risk of ischemic stroke and 1.6-fold increase in the risk for total stroke among women with BMI ≥32 kg/m² compared with women with BMI <21 kg/m².12 As in the present study, inclusion of hypertension, diabetes, and elevated cholesterol led to substantial attenuation of the risk estimates. There was also a suggestion of an inverse association between BMI and hemorrhagic stroke that also did not reach statistical significance. Similar to the present findings, the highest risk for hemorrhagic stroke was seen among women in the leanest BMI category. The study further evaluated weight change and found increased risk for total and ischemic stroke but not for hemorrhagic stroke among women who gained >11 kg.12 Studies that found no association between obesity and stroke may have been limited by small size32 or may have controlled for the potential biological mediator of hypertension.31,33

In men, a number of studies support an association between BMI and increased risk of stroke.9,10,21,34 A recent population-based study from Göteborg, Sweden, found a 2-fold increase in the risk for total, ischemic, and undetermined stroke for men with BMI >30 kg/m² compared with men with BMI of 20.0 to 22.5 kg/m².9 No association was observed between BMI and hemorrhagic stroke. Because that study showed a strong association between BMI and undetermined stroke, it is possible that some of these cases were in fact hemorrhagic strokes and that the association between BMI and hemorrhagic stroke was thus underestimated. Data from the Physicians’ Health Study showed a significant increase in the risk of total, ischemic, and hemorrhagic stroke with increasing BMI.10 Men with BMI ≥30 kg/m² had a >2-fold risk increase for all stroke types. In both studies, the increased risk for total and ischemic stroke, although attenuated, remained statistically significant when additionally controlled for hypertension, diabetes, and elevated cholesterol.

The association between obesity and hemorrhagic stroke remains unclear. The present study is consistent with findings of others that showed an increased risk of hemorrhagic stroke among the lean.12,14,19 Other studies, however, found no association9,20,21 or an increased risk with increasing BMI.10 The fact that the incidence of hemorrhagic stroke is higher in Asian populations has led to the hypothesis that low cholesterol, in addition to lean body weight, may be associated with increased risk of hemorrhagic strokes.20,35 The low numbers of hemorrhagic strokes in most of the studies may explain in part the uncertainty with regard to the association between BMI and hemorrhagic stroke. Future studies are needed to determine whether lean BMI and/or low cholesterol or other factors are important contributors to hemorrhagic stroke.

There is an ongoing discussion about the best measure of obesity for stroke prediction.11,30,32,36 A report from the Northern Manhattan Stroke Study suggested that abdominal obesity, as measured by the waist-to-hip ratio, was a stronger predictor than BMI and had a greater effect among younger individuals.11 In that study, however, obesity was evaluated at the time of the stroke, which may indicate that abdominal obesity may be a better short-term predictor than BMI.
Nevertheless, obesity is a strong risk factor for total and ischemic stroke regardless of the measure used. Whether more detailed information on body fat distribution will lead to better prediction of stroke currently remains unclear.

Obesity is a strong risk factor for the development of hypertension, diabetes, and elevated cholesterol. In virtually all studies that have evaluated the association between obesity and ischemic stroke, hypertension, diabetes, and elevated cholesterol were biological mediators. This, however, should not downplay the importance of obesity as a primary risk factor for stroke. To the contrary, because obesity has such a strong influence on hypertension and diabetes, obesity may be the biggest overall contributor to stroke occurrence. In some studies, a statistically significant excess risk for stroke remained even after controlling for hypertension, diabetes, and elevated cholesterol. In a recent large, population-based study from Malmö, Sweden among normotensive men and women, BMI was a statistically significant and independent predictor for stroke. Furthermore, the risks of excessive body fat for stroke can be obscured by a history of cigarette smoking and thinness associated with deteriorating health.

In addition to the established mechanisms by which BMI affects stroke risk such as hypertension and diabetes, other mechanisms may be associated with the increased risk. Some investigators have proposed that an increase in prothrombotic factors observed among overweight and obese individuals may contribute to their increased risk for ischemic events. Increased levels of C-reactive protein in overweight and obese individuals may also play a role in their increased risk of stroke, because an association between increased levels of inflammatory markers and risk of ischemic stroke has been documented; however, the biological interrelationship between obesity, inflammatory markers, and ischemic stroke risk has yet to be determined.

The present study has several strengths, including the prospective method of data collection, the large size of the study population, the large number of incident strokes, the high rate and length of follow-up, and the homogeneous nature of WHS participants, which reduces potential confounding by access to medical care and other socioeconomic factors. On each of the follow-up questionnaires, WHS participants were asked specifically about stroke and transient ischemic attacks. Because stroke was a major end point of the WHS trial, all efforts were made to obtain the relevant medical records, and an experienced End Points Committee confirmed stroke cases only after review of these records. In addition, the interobserver agreement in the classification of stroke was excellent. We further ran several different models, including time-varying models, to update the most recent exposure information, used different cutpoints of BMI, and evaluated potential biological mediators and effect modifiers.

Several limitations should be considered when evaluating the present results. First, information on body weight and height, as well as on all potential confounders, was self-reported, and thus nondifferential misclassification is possible. Participants of the WHS, however, were all health professionals, who are known to accurately report information regarding lifestyle factors and health status. Specifically, self-reported and directed measured weight were highly correlated (r=0.96) in another comparable cohort of female health professionals. In addition, nondifferential misclassification in a prospective study most likely would lead to an underestimation of the association between BMI and stroke. We have no reason to believe that a significant number of participants did not report a stroke event and particularly no reasoning that such potential underreporting would be differential with regard to BMI status. Second, because participants in the WHS were all health professionals who participated in a randomized trial, and the vast majority (94.9%) of them were white, the present results may not necessarily be extrapolated to other populations; however, we have no a priori basis for believing that the biological mechanisms by which BMI may lead to stroke differ in the WHS cohort compared with other populations. In addition, the relative measures of effect for a wide variety of cardiovascular risk factors have been similar to those seen in other studies. Because women participating in the WHS were somewhat leaner than the general population, we may have underestimated the risk of heavier populations. Finally, as with all observational studies, residual and unmeasured confounding remains an alternative explanation for our findings, despite adjustment for many potential confounders.

In conclusion, our study indicates that obesity is associated with increased risk of total and ischemic stroke. This was not modified by age, smoking, or exercise and was strongly mediated by hypertension, diabetes, and elevated cholesterol, which may be biological intermediates of the obesity–stroke association. The association between BMI and hemorrhagic stroke remains less clear. Preventing obesity may lead to a substantial reduction of total and ischemic stroke occurrence.

Acknowledgments

The study was supported by the National Institutes of Health (CA-47988 and HL-43851), Bethesda, Md. We are indebted to the participants in the Women’s Health Study for their outstanding commitment and cooperation, to the entire Women’s Health Study staff for their expert and unfailing assistance, and to Gregory Kotler for programming assistance.
