Gastrointestinal Complications of Dual Antiplatelet Therapy
Neelima G. Vallurupalli, MD; Samuel Z. Goldhaber, MD

Case presentation: A 59-year-old man with a history of hypertension, dyslipidemia, and smoking was hospitalized with acute coronary syndrome requiring emergency percutaneous coronary intervention with 4 drug-eluting stents. His discharge medications included dual antiplatelet therapy with aspirin 325 mg/d and clopidogrel 75 mg/d. Three weeks after discharge, he returned to the Emergency Department with bloody stools and a hematocrit of 23% (previously 36%) and required 3 US of packed red blood cells. Endoscopy showed a bleeding duodenal ulcer with adherent clot (Figure).

Background
We prescribe dual antiplatelet therapy with aspirin and clopidogrel to prevent and treat cardiovascular, cerebrovascular, and peripheral arterial disease. According to American Heart Association statistics, 700,000 patients had stroke, 13 million had coronary artery disease, and 8 to 12 million suffered from peripheral arterial disease in 2002. Each year, 1.2 million patients in the United States receive dual antiplatelet therapy for various vascular conditions such as coronary artery disease, transient ischemic attack, thrombotic stroke, and peripheral vascular disease probably exceeds several million.

The use of aspirin compared with placebo reduces the risk of myocardial infarction, stroke, or death from vascular causes by approximately 25%. In the Clopidogrel Versus Aspirin in Patients at Risk of Ischemic Events (CAPRIE) trial, administration of clopidogrel decreased the relative risk of vascular events by 8.7% compared with aspirin. The addition of clopidogrel to aspirin in patients with acute coronary syndrome reduces the risk of reinfarction, stroke, and death by 20% compared with aspirin alone.

The net benefit from using dual antiplatelet therapy in high-risk vascular disease patients comes at the cost of increased gastrointestinal (GI) complications. Major complications include gastroduodenal ulcerations that can lead to GI hemorrhage, perforation, and death. Minor complications include dyspepsia, pill esophagitis, subepithelial hemorrhages, erosions, and ulcerations in the stomach and duodenum. Patients at especially high risk for GI complications while on antiplatelet therapy are the elderly; those with a history of gastroduodenal ulcers, gastroesophageal reflux disease, esophagitis, untreated Helicobacter pylori infection, intestinal polyps, or cancer; and those using concomitant anticoagulants, steroids, or nonsteroidal anti-inflammatory drugs.

Risk of GI Complications With Aspirin
The suppression of gastroduodenal mucosal prostaglandin synthesis is one of the important mechanisms of mucosal damage by aspirin. Serious GI ulcer complications are 2- to 4-fold more common in patients who take 75 to 300 mg/d of aspirin compared with controls. Aspirin doses as low as 10 mg/d can significantly decrease the gastric mucosal prostaglandin level and cause gastric erosions. During a 4-year period in the United Kingdom Transient Ischemic Attack study, GI complications in patients taking aspirin ranged from mild dyspepsia (31%) to life-threatening bleeding and perforation (3%).

While examining the relationship between aspirin intake and hospitalization with peptic ulcer bleeding, Weil et al found that all doses of aspirin are associated with an increased risk of GI bleeding. The risk of GI bleeding was dose related: odds ratio 2.3 for 75 mg/d, 3.2 for 150 mg/d, and 3.9 for 300 mg/d. The risk of upper GI bleeding for plain, enteric-coated, or buff-
ered aspirin did not differ. Long-term aspirin therapy, even at a low dose (50 to 162.5 mg/d), may cause overt GI bleeding.

Risk of GI Complications With Clopidogrel
It is unclear how clopidogrel causes GI erosions or ulcerations. Clopidogrel has no effect on the cyclooxygenase pathway and therefore acts independently of aspirin. In a retrospective analysis, the frequency of GI bleeding in a high-risk population with prior peptic ulcer disease was 12%.11

Risk of GI Complications With Dual Antiplatelet Therapy
The risk of overt GI bleeding with dual antiplatelet therapy can be as high as 1.3% within the first 30 days of therapy.2 In the Clopidogrel for Unstable Angina to Prevent Recurrent Events (CURE) study, Peters et al12 showed that the risk of bleeding increases with increasing dose of aspirin with or without clopidogrel. The dose of clopidogrel remained fixed at 75 mg/d. At the highest dose of aspirin (≥200 mg) given with placebo, bleeding was higher (3.7%) than the risk of GI bleeding with the combination of clopidogrel and aspirin in the lowest-dose (≤100 mg) group (3.0%).

Efficacy of Dual Antiplatelet Therapy
Drug-eluting stents have become the standard of care for percutaneous coronary intervention to reduce the risk of in-stent restenosis. However, in-stent thrombosis, a catastrophic and potentially fatal complication, may occur more often with drug-eluting than bare metal stents. The strongest predictor of stent thrombosis is discontinuation of antiplatelet therapy, exceeding other independent predictors such as renal failure, bifurcation lesions, diabetes, and low ejection fraction.13 Hence, after percutaneous coronary intervention with drug-eluting stents, aspirin is prescribed lifelong and clopidogrel is prescribed for at least 3 months.14 However, McFadden et al15 reported 4 cases of late stent thrombosis occurring as late as 442 days after implantation of drug-eluting stents and resulting in myocardial infarction when antiplatelet therapy was discontinued. Late thrombosis seen with drug-eluting stents is attributed to delayed vascular healing and delayed re-endothelialization, rendering the stent prothrombotic. Some cardiologists continue patients on antiplatelet therapy indefinitely if no adverse bleeding events are encountered.

Aspirin and clopidogrel “resistance” has been increasingly identified with the availability of point-of-care platelet aggregation tests. Many patients on aspirin and clopidogrel therapy do not achieve the desired level of platelet inhibition. One way to overcome aspirin and clopidogrel resistance is to use higher loading and maintenance doses.

The inhibition of platelet aggregation by clopidogrel is dose dependent. A higher loading dose of clopidogrel is now being used more often than the conventional 300-mg dose because of more rapid and higher levels of platelet inhibition. Patti et al16 reported that a 600-mg loading dose was safe and more effective in reducing periprocedural infarction than a 300-mg loading dose.

Monitoring and Diagnosis of GI Complications
Several methods can be used to monitor and diagnose occult and overt GI complications of dual antiplatelet therapy. The tests range from least specific (fecal occult blood test) to the gold standard of traditional endoscopy. Patients can also be monitored for clinical symptoms such as dyspepsia or bloating by using a symptom diary or a validated scoring system similar to the Gastrointestinal Symptoms Rating Scale questionnaire (Table). A noninvasive imaging test that does not require sedation to diagnose occult GI complications is the PillCam ESO capsule endoscopy (Given Imag-
H₂ antagonists reversibly block H₂ receptors on the basolateral membrane of gastric parietal cells. Until the early 1990s, H₂ antagonists were the mainstay of pharmacotherapy for the prevention and management of upper GI bleeding. Between 1984 and 2000, 32 randomized controlled trials compared H₂ antagonists with placebo. Agents evaluated in these studies included cimetidine, ranitidine, and famotidine. Many were limited by a small sample size and unsatisfactory study design.

Factors limiting the utility of H₂ antagonists include the development of tachyphylaxis, the need for dosage adjustment in renal insufficiency, and side effects such as thrombocytopenia and mental status abnormalities.

The introduction of PPIs has led to a safer and more effective strategy in the prevention and management of GI ulceration. PPIs irreversibly inhibit hydrogen ion pumps in gastric parietal cells. PPIs block the final step of acid production, negate stimulation of gastric secretion, and lead to prolonged acid suppression.

Yeomans et al. showed that omeprazole, a PPI, is more effective than H₂ receptor antagonists in suppressing gastric acid, preventing ulcers, and healing ulcers that are related to chronic use of nonsteroidal anti-inflammatory drugs such as aspirin.
agents were stopped for 1 day during the upper GI bleeding, they were resumed immediately when active bleeding stopped. He was discharged home on a PPI along with antiplatelet therapy.
