Larger Cell Size in Rabbits With Heart Failure Increases Myocardial Conduction Velocity and QRS Duration

Background—Patients with heart failure (HF) have an increased QRS duration, usually attributed to decreased conduction velocity (CV) due to ionic remodeling but which may alternatively result from increased heart size or cellular uncoupling. We investigated the relationship between QRS width, heart size, intercellular coupling, and CV in a rabbit model of moderate HF and in computer simulations.

Methods and Results—HF was induced by pressure-volume overload. Heart weight (21.1±0.5 versus 10.2±0.4 g, mean±SEM; P<0.01) and QRS duration (58±1 versus 50±1 ms; P<0.01) were increased in HF versus control. Longitudinal CV (θL; 79±2 versus 67±4 cm/s; P<0.01) and transversal subepicardial CV (θT; 43±2 versus 37±2 cm/s; P<0.05) were higher in HF than in controls. Transmural CV (θTM) was unchanged (25±2 versus 24±1 cm/s; P=NS). Patch-clamp experiments demonstrated that sodium current was unchanged in HF versus control. Immunohistochemical experiments revealed that connexin43 content was reduced in midmyocardium but unchanged in subepicardium. Myocyte dimensions were increased in HF by ~30%. Simulated strands of mammalian ventricular cells (Luo-Rudy dynamic model) revealed increased θL and θT with increased myocyte size; however, increased CV could not compensate for increased strand size of longitudinally coupled cells, and consequently, total activation time was longer.

Conclusions—Increased myocyte size combined with the observed expression pattern of connexin43 yields increased θL and θT and unchanged θTM in our nonischemic model of HF. A hypertrophied left ventricle together with insufficiently increased θL and unaltered θTM results in a prolonged QRS duration. (Circulation. 2006;113:806-813.)

Key Words: hypertrophy ■ heart failure ■ electrocardiography ■ myocytes ■ conduction

Patients with heart failure (HF) have a poor prognosis. Mortality is high, and ~50% of patients with HF die suddenly, which suggests an arrhythmogenic origin.1,2 Patients with HF often reveal increased QRS duration3,4 and those with QRS duration >150 ms have a higher cardiac mortality rate than patients with shorter QRS duration.4,5 Increased QRS duration is commonly interpreted as slowing of ventricular conduction. Although slow conduction is one of the prerequisites for the occurrence of reentrant arrhythmias6 and therefore may explain the increased propensity of patients with HF for life-threatening arrhythmias,1,2 studies on conduction velocity (CV) in HF are contradictory.

Clinical Perspective p 813

In animal studies, unchanged CV7,8 and decreased CV9 have been reported in the setting of HF. QRS duration was increased10 and CV decreased11 in a guinea pig model of HF at day 150 after aortic banding; however, in the same model, CV was increased after 50 days of aortic banding.11 This underscores the dynamic nature of HF. In 2 other studies that included patients with HF, an increased CV was measured12,13 as well. Increased CV was also found in hypertrophied hearts.11–13 In hypertrophy, cell size increases. We hypothesized that increased cell size underlies both the increase in CV and the increase in QRS duration. The latter would increase because it takes more time to activate the hypertrophied ventricles, despite the increase in CV. The aim of the present study was to document CV changes and to correlate CV with QRS duration, connexin43 (Cx43) content, and cell size in an established nonischemic model of moderate HF,14 in which hypertrophy is the predominant feature and in which electrical remodeling is negligible. The functional effects of the experimentally observed changes in cell size were assessed with computer simulations at various preset values of intercellular coupling.
Methods

Rabbit Model of HF

The experimental protocol complied with the “Guide for the Care and use of Laboratory Animals” published by the US National Institutes of Health (NIH publication 85-23, revised 1985) and was approved by the institutional animal experiments committee. HF was induced by combined volume and pressure overload in 2 sequential surgical procedures in New Zealand White rabbits as described previously.14 In that study,14 differences between nonoperated and sham-operated animals were negligible. Thus, for the present study, control rabbits were not sham-operated. Before the first operation, a 3-lead ECG was recorded in rabbits premedicated with ketamine (100 mg/mL, 0.7 mL/kg body weight IM) and xylazine (20 mg/mL, 0.3 mL/kg body weight IM). Control and HF rabbits (at 8 months of age or when HF with overt signs of dysnea developed) were weighed, a 3-lead ECG was recorded, and left ventricular end-diastolic pressure was measured as described previously.14 Rabbits were heparinized (1000 IU IV) and killed by injection of pentobarbital (60 mg/mL, 5 mL IV). Hearts were isolated and submerged in Tyrode’s solution (4°C; for composition, see below). Presence of ascerts and heart and lung weights were documented.

Perfusion of Hearts

After excision of the heart, the aorta was prepared free from adjacent tissue. In control hearts, a cannula was inserted into the aorta to allow retrograde perfusion of the heart. Because retrograde perfusion is impossible owing to aortic insufficiency in HF, both coronary arteries were cannulated separately. The hearts were perfused with Tyrode’s solution containing (in mmol/L) 130 NaCl, 5.6 KCl, 2.2 CaCl₂, 0.55 MgCl₂, 24.2 NaHCO₃, and 11.1 glucose, saturated with 95% O₂ and 5% CO₂. Myocardial temperature was maintained at 37°C.

Activation Mapping and CV

Activation times (ATs) were derived from local electrograms recorded with an epicardial multielecetrode (247 unipolar electrode terminals, 1.5 × 1 mm interelectrode distance) and/or with 4 intramural needles (8 electrode terminals/needle, interelectrode distance 0.3 mm) inserted 1 cm apart in a square on the left ventricular free wall. Electrodes were connected to a data-acquisition system (Bio-semi Mark-6). A virtual ground electrode was connected to the aortic root. Data of 1.8-second episodes (sampling interval 0.5 ms) were stored on disk. Local AT, defined as the moment of the maximum negative dV/dt, was determined with a custom interactive analysis program.15 Pacing from the center of the epicardial multielecetrode or from the most distal located electrode on a needle was performed with rectangular current pulses at diastolic stimulation threshold (2-ms duration) at a basic cycle length of 250 ms.

Subepicardial activation maps were constructed, and longitudinal (θₓ) and transversal (θᵧ) CVs were calculated from the ellipsoid activation pattern as described previously.16 Transmural CV (θ_txn, perpendicular to the epicardial surface) was calculated from local ATs measured on 1 needle.

Sodium Current

The fast sodium current (I₅Na) is responsible for the action potential upstroke and is important for CV.17 Therefore, I₅Na was evaluated by whole-cell patch-clamp experiments. The pipette and bath solutions contained (in mmol/L) NaCl 140, KCl 5.4, CaCl₂ 1.8, MgCl₂ 1.0, glucose 5.5, and HEPES 5.0 (pH 7.3 [NaOH]). The pipette command potential was corrected for the resting membrane potential (Vm) of the myocytes, which was −81.5 ± 0.9 and −81.7 ± 0.6 mV in control (n=37) and failing (n=32) myocytes, respectively, determined in a separate set of whole-cell patch-clamp experiments. I₅Na was defined as the difference between peak current and the current at the end of the depolarizing voltage step.

Myocyte Dimensions

The size of individual left ventricular myocytes was determined in 6 control and 7 HF animals. Enzymatically isolated myocytes were studied in a cell chamber on the stage of an inverted microscope during superfusion with a HEPES solution containing (in mmol/L) NaCl 148, NaHCO₃ 1.0, KHCO₃ 3.3, K₂HPO₄ 1.4, MgCl₂ 1.9, CaCl₂ 1.3, glucose 11.0, HEPES 16.8 (37°C, pH 7.3 [NaOH]). Cellular length and width were measured at a resolution of 3 μm in 50 randomly selected viable rod-shaped myocytes per heart.

Immunohistochemistry and Histology

Cryosections (10-μm thickness) perpendicular or parallel to the epicardial surface were made from the same area as the CV measurements. Perpendicular sections incubated with rabbit polyclonal anti-Cx43 antibody (Zymed) and mouse monoclonal anti-N-cadherin antibodies (Sigma) were obtained by the method described previously.21 Immunolabeled sections were mounted in Vectashield mounting medium (Vector Laboratories) and examined with a light microscope with epifluorescence equipment (Nikon Optiphot-2). Presence of fibrosis was analyzed from parallel sections fixed with 4% paraformaldehyde and stained with picrosirius red. Images from 6 randomly selected fields per section viewed with light microscopy were digitized, and the amount of fibrosis was analyzed with Image Pro Plus (version 5.02, Media Cybernetics).

Computer Model

We assessed θₓ and θᵧ in linear strands of 100 longitudinally or transversally coupled subepicardial myocytes. Individual cells of the strands were described with the Luo-Rudy dynamic model of mammalian subepicardial ventricular myocytes (LRd model),22 including the transient outward current Ito.23 As in other studies,24,25 entire cell length (for longitudinal conduction) or width (for transversal conduction) was used as the spatial discretization element in our computations, with elements connected by the lumped myoplasmic resistance (calculated from the myocyte dimensions and the myoplasmic resistivity of 150 Ω/cm) and gap junctional resistance (calculated from the myocyte dimensions and the gap junctional resistivity).

Action potential propagation was elicited by injection of an ~20% suprathreshold current pulse (duration 2 ms) into the first cell of the strand, at a frequency of 4 Hz. The activation wave of the sixth action potential was analyzed.

We assumed that membrane ionic channel density per unit of membrane surface area did not change with increased cell size. We ran simulations at normal and reduced intercellular coupling with control and HF cell dimensions, assuming that cell shape was that of a rectangular box. CV and total AT per myocyte were calculated from the difference in AT of cell 20 and cell 80.

Statistical Analysis

Data are presented as mean±SEM. A 1-way ANOVA with the Student-Newman-Keuls test for post hoc analysis was used to test for a significant differences of θₓ, θᵧ, θtxn, stimulation threshold, QRS duration, myocyte length and width, resting membrane potential, and sodium current density (either whole-cell or cell-attached patch clamp) in HF compared with control hearts. When data were not normally distributed or variance was not equal, a Kruskal-Wallis 1-way ANOVA on ranks with Dunn’s test for post hoc analysis was...

HF Parameters

Table 1 shows characteristics of HF. There were 3 experimental groups: (1) measurement of CVs (control n=8; HF n=15), (2) myocyte dimensions (control n=6; HF n=7), and (3) patch-clamp experiments (control n=8; HF n=22). In Table 1, data from control (n=22) or HF (n=44) animals from each experimental group were lumped together because there were no significant differences between the parameters in the 3 subgroups. HF is present as evident from the presence of ascites and the increase in (relative) heart weight, relative lung weight, and left ventricular end-diastolic pressure compared with control.

QRS Duration

QRS duration (Table 1) was 58±1 ms (mean±SEM) in HF. This was longer than in the same animals before the first operation (49±1 ms) and in control animals (age 8 months; 50±1 ms; ANOVA, P<0.01).

Conduction Velocity

Figures 1A and 1B shows representative subepicardial activation maps. Both θl and θr were higher in HF than in control. This is also evident from the 15-ms isochrone (bold line), which encloses a larger area in the activation map of the HF than the control rabbit. The stimulation threshold was not different between HF (165±33 μA) and control 164±25 μA (ANOVA, P=NS). Average θl and θr (Table 2) were higher in HF than in control animals. θtrans was not different between control and HF animals (Table 2).

Sodium Current

Figure 2 shows representative whole-cell patch-clamp (Figure 2A) and cell-attached macropatch (Figure 2B) INa recordings from control and HF cells. Current density and current-voltage relationship (Figure 2B) were not different in HF compared with control in either condition (Figures 2C and 2D).

Cx43 and Fibrosis

Figure 3A shows normal Cx43 expression in all 3 layers of a control heart, which is accompanied by an almost identical pattern of N-cadherin expression (mechanical junction). Figure 3B shows a typical pattern of Cx43 in a heart from a rabbit with HF. Expression in the subendocardium (6/6 hearts) and the subepicardium (5/6 hearts) is similar to control. Cx43 (but also N-cadherin) in the midmyocardium is reduced (6/6 hearts). In 1 heart, epicardial Cx43 was reduced, although not to the level depicted for the midmyocardium. The total amount of fibrosis was not different between control (21±1%, n=4) and HF (20±2%, n=10; Kruskal-Wallis, P=NS).

Myocyte Dimensions

Myocyte length and width were measured in 6 control and 7 HF rabbits (50 myocytes/heart). Figure 4 shows that myocyte length (191.7±3.7 versus 144.9±2.4 μm, respectively) and width (32.7±1.1 versus 25.2±0.5 μm, respectively) were both increased by ~30% in HF compared with control (ANOVA, P<0.05).

Simulation Studies

We performed computer simulations (Figure 5) to test whether the experimentally observed increase in myocyte

dimensions (see Figure 4) can explain the HF-induced increase in $\theta_L$ and $\theta_T$, as well as the increase in total AT as indicated by the increase in QRS duration. First, we ran simulations with cell length and width set to 144.9 and 25.2 $\mu$m, respectively, ie, the mean values observed for control myocytes. We found that total gap junctional conductance values of 4 and 15 $S$ were required to obtain the experimentally observed $\theta_L$ and $\theta_T$, respectively. These values of 4 and 15 $S$ correspond with a gap junctional resistivity ($R_j$) of 1.59 and 2.43 $\Omega/cm^2$, respectively, and were regarded as 100% of intercellular coupling.

Next, we ran simulations with cell length and width set to 191.7 and 32.7 $\mu$m, respectively, ie, the mean values observed for failing myocytes. We assumed that the number of gap junction and membrane ionic channels per unit membrane surface did not change. Figure 6 shows simulated CV (Figures 6A and 6B) and total AT per myocyte (Figures 6C and 6D). Longitudinal CV (Figure 6A) increased from 68 cm/s (control) to 81 cm/s (HF) at 100% intercellular coupling; however, the 19% increase in $\theta_L$ was not enough to fully compensate for the 32% increase in myocyte length, and therefore, total AT/myocyte (Figure 6C) was larger in HF than control (237 versus 213 $\mu$s, 11% increase). Transversal CV (Figure 6B) was 37 cm/s in control and 47 cm/s in HF animals at 100% intercellular coupling. The 27% increase in $\theta_T$ was large enough to almost completely compensate for the 30% increase in cell width. Total AT per myocyte in the strand of transversally coupled cells (Figure 6D) changed from 68 $\mu$s in control to 70 $\mu$s in HF animals (2.5% increase) at 100% intercellular coupling. To test the dependence of our simulation results on the degree of intercellular coupling, we repeated our simulations at 20%, 40%, 60%, and 80% intercellular coupling, respectively. Reduced coupling resulted in reduced CV, but at every identical simulated value for intercellular coupling, CV was larger in HF cells than in control cells. The dashed horizontal lines in Figures 6A and 6B show that the CV in HF cells with a coupling of 50% to 60% is similar to that of control cells with 100% intercellular coupling.

Discussion

In a nonischemic rabbit model of moderate HF compared with control, (1) QRS duration, $\theta_L$, $\theta_T$, and myocyte length and width are increased; (2) $\theta_{max}$, sodium current density, fibrosis, and subepicardial Cx43 expression are unchanged; and (3) midmyocardial Cx43 expression is reduced. Computer simulations demonstrate that the increased cell size results in increased CV at any level of intercellular coupling; however, $\theta_L$ and $\theta_{max}$ are not large enough to compensate for the increase in ventricular dimensions in HF and thus result in an increased QRS width.
QRS Duration
QRS prolongation occurs in patients with HF and is associated with increased cardiac mortality. In patients with dilated cardiomyopathy, QRS duration increases progressively. This indicates that even in the presence of complete bundle-branch block, increased left ventricular mass with increased CV may cause an increase in QRS duration, although it cannot be excluded that conduction is slowed in more severe HF. Indeed, in a study of individuals free of HF and myocardial infarction, QRS duration was positively correlated with left ventricular mass and dimensions.

Sodium Current
In cell-attached patches, $I_{Na}$ was unchanged in HF compared with control animals (Figure 2B). This indicates that the brain-type sodium channels, located in T-tubules, do not change in HF (Figure 2B). Whole-cell $I_{Na}$, carried by both myocardial-type (located in the intercalated disk) and brain-type sodium channels, is also not changed in HF (Figure 2A). Any change in CV is therefore attributable to changes in other parameters. In contrast, $I_{Na}$ peak current density was decreased in other models. This may imply that patients with severe HF have a reduced CV that contributes to QRS prolongation.

Intercellular Coupling and Fibrosis
Reduction of Cx43 may contribute to slowing of conduction. Cx43 expression is reduced in the left ventricle of patients with hypertrophic, dilated, or ischemic cardiomyopathies. These studies did not specifically report on subepicardial Cx43 expression. In the present study, we observed reduced Cx43 expression in left ventricular midmyocardium but not in subepicardium. In contrast, in a canine model of rapid pacing–induced HF, Cx43 expression was reduced, especially in the subepicardial layer. However, in dogs with left bundle-branch block–related left ventricular dyssynchrony, the lateral wall showed no change in subepicardial Cx43 expression. Lower Cx43 expression levels in subendocardium compared with subepicardium were further exaggerated in dogs with left bundle-branch block associated with HF compared with controls. A transmural gradient of Cx43 expression was present in mice but not in rats. Apparently, the transmural gradient of Cx43 expression differs and changes within the heart, between species, and with the underlying disease.

Tissue architecture and amount of fibrosis can affect activation propagation in the setting of HF; however, fibrosis was not increased in the present model of HF. Structural remodeling (except for hypertrophy) was also absent because no infarction was made.

Conduction Velocity
In guinea pig after 150 days of aortic constriction, heart size, QRS duration, and intracellular resistivity were increased and CV was decreased. In a milder stage of HF (50 days of...
aortic constriction), heart size and CV were increased, whereas intracellular resistivity and QRS width were unchanged. Other studies reported a decreased subepicardial CV in the setting of HF or no change. In the present animal model, we were able to directly relate CV to the increased cellular dimensions in subepicardium, where Cx43 was unchanged; however, this increased subepicardial CV (combined with unaltered $\theta_{TM}$) was not enough to compensate for the increase in myocyte dimensions and hence resulted in an increased QRS duration. The data obtained in guinea pig illustrate the dynamic nature of HF. In the present model, HF is moderate and electrical remodeling is absent, except for transient outward K$^+$ current density (data not shown). This makes it an ideal model to address the effect of hypertrophy.

In the present study, $\theta_{TM}$ was not changed. In contrast, Toyoshima et al. showed that $\theta_{TM}$, calculated by dividing the left ventricular wall thickness by the interval between onset of the QRS complex and the moment of epicardial breakthrough, is increased in hypertrophy, whereas in a canine model of rapid pacing–induced HF, $\theta_{TM}$ was decreased. The discrepancy between these results might be due to differences in the amount of Cx43 expression or electrical remodeling.

Myocyte Dimensions and Simulations
In our computer model, axial resistivity is decreased owing to pathophysiological growth and results in increased CV. Increase in cell length in a similar model but one that compared adult with neonatal myocytes (wild-type and Cx43$^{-/-}$ mice) also resulted in decreased axial resistivity and increased CV.

In canine ventricle, normal physiological growth increased myocyte length and width and $\theta_l$ and $\theta_t$ in adult dogs compared with neonatal animals. The gap junction distribution also changed with aging. Computer simulations demonstrated that increase in myocyte size and Cx43 distribution are sufficient to account for the experimental results and that cell size is at least as important as Cx43 distribution in transversal propagation.

The simulations in the present study show that the increase in $\theta_t$ may compensate for the increased dimensions of the preparation, whereas the increase in $\theta_l$ does not compensate for the increased length of the preparation and results in a longer total AT. Our simulations with subepicardial cells indicate that specific combinations of reduced intercellular coupling and increased myocyte size may yield an unchanged CV in HF, despite changes in both underlying parameters (cf the dashed lines in Figures 6A and 6B). This may also explain the unchanged $\theta_{TM}$ despite reduced midmyocardial Cx43 levels in our rabbit model.

Clinical Implications
QRS prolongation may be associated with increased or normal CV in patients with HF/hypertrophy; however, the potential antiarrhythmic effect of increased CV in patients with HF/hypertrophy may be offset by a disproportional increase in myocardial mass, which favors the onset of reentrant arrhythmias.

Study Limitations
We directly compared CV of 2D measurements with 1D simulations. In the measurements, we used point stimulation, whereas our 1D simulations correspond with plane wave stimulation in 2D. Therefore, our measurements are subject to underestimation of planar CV due to wave-front curvature. Nevertheless, it is clear that the increase in cell size and CV are directly related. We used 1D simulations with rectangular boxlike cells, which does not reflect the mixed contribution of longitudinal and transverse gap junctions in interdigitating cell bundles. Length and width but not thickness of the myocyte could be measured with light microscopy. We used the width of the myocyte as an estimate for the thickness, but we cannot exclude an overestimation.
Our model of HF is relatively mild and focused on hypertrophy, although ascites is a predominant feature. The model permits study of increases in cell size and decreases in intercellular coupling. In more severe stages of HF, additional factors such as fibrosis or electrical remodeling also contribute to pathophysiological changes. A major cause of HF is ischemia related. We chose a model of combined volume/pressure overload to exclude infarcted tissue as a confounding factor. Studies in explanted hearts involve patients who were in the end stage of HF, whereas our model reflects a moderate stage of HF. Thus, conclusions derived from this particular model do not necessarily apply to other HF models.

Conclusions
QRS prolongation was associated with increased heart size and increased dimensions of left ventricular myocytes in our nonischemic rabbit model of moderate HF. Also, the animals with HF had higher left ventricular subepicardial CVs than control animals, without any change in sodium current density. Our computer simulations demonstrated that the increase in myocyte dimensions per se may explain the increase in subepicardial CV and the unchanged $\theta_{SD}$ despite the reduction in midmyocardial Cx43 expression. Although subepicardial CV was increased and $\theta_{TM}$ unchanged, this was not enough to compensate for increased heart size. This explains the increased QRS duration, as corroborated by our simulation study in which total AT was longer in longer strands with the same number of cells.

CLINICAL PERSPECTIVE

The width of the QRS complex is associated with the duration of complete activation of the ventricles. In hypertrophy and heart failure, QRS duration is increased. Generally, this increase is interpreted as a decrease in ventricular conduction velocity. We recorded QRS duration and measured conduction velocity (longitudinal, transversal, and transmural) in the left ventricle in an animal model of hypertrophy/heart failure. Additionally, we measured the size of left ventricular myocytes and studied the expression pattern of connexin43 in the left ventricle. QRS duration was increased in animals with heart failure compared with controls. Myocyte dimensions were increased. Connexin43 expression remained normal in subepicardium but was reduced in midmyocardium. Transmural conduction velocity was unaltered, and longitudinal and transversal subepicardial conduction velocities were increased. Computer simulations demonstrated that an increase in myocyte dimensions per se may explain the increase in subepicardial conduction velocity. Additionally, the increase in myocyte size in combination with the reduction in midmyocardial connexin43 expression may explain the unchanged transmural conduction velocity. Although subepicardial conduction velocity is increased and transmural conduction velocity unchanged, this is not enough to compensate for increased heart size, and hence QRS duration is increased. Therefore, a wide QRS complex, as observed, for example, in patients with heart failure, does not necessarily indicate slow ventricular conduction but can also be due to hypertrophy alone, which increases the total time required to activate the ventricles.
Larger Cell Size in Rabbits With Heart Failure Increases Myocardial Conduction Velocity and QRS Duration
