Contemporary Reviews in Cardiovascular Medicine

New Insights Into Pacemaker Activity
Promoting Understanding of Sick Sinus Syndrome

Halina Dobrzynski, PhD; Mark R. Boyett, PhD; Robert H. Anderson, MD, FRCPath

Sick sinus syndrome is an abnormality involving the generation of the action potential by the sinus node and is characterized by an atrial rate inappropriate for physiological requirements. Manifestations include severe sinus bradycardia, sinus pauses or arrest, sinus node exit block, chronic atrial tachyarrhythmias, alternating periods of atrial bradyarrhythmias and tachyarrhythmias, and inappropriate responses of heart rate during exercise or stress. Although its incidence increases in an exponential-like manner with age, it can occur at all ages, including in the newborn. The mean age of patients with the syndrome is 68 years, with both genders being affected in approximately equal proportion. The syndrome occurs in 1 of every 600 cardiac patients older than 65 years and accounts for approximately half of implantations of pacemakers in the United States. The syndrome is a collection of conditions, with a variety of causes intrinsic or extrinsic relative to the node. Age-dependent degenerative fibrosis of the tissues of the node has been suggested to be a common cause, although this is disputed. Clinical aspects of the syndrome have been reviewed many times. In this review, coinciding with the centenary of the discovery of the sinus node, we offer new insights into intrinsic causes that come from an understanding of the mechanisms underlying pacemaking.

Centenary of Discovery of Sinus Node

It is now exactly 100 years since Arthur Keith (Figure 1A) performed the work that introduced the world to the location of the sinus node. Keith had been intrigued by the actions of the musculature of the heart and was anxious to establish any muscular mechanisms involved in closure of the great caval veins as the right atrium contracted to deliver its load to the ventricles. He was aware of the work of James Mackenzie, then a medical practitioner working in the north of England, and posed to Mackenzie the following question: “Are the caval venous openings closed when the right auricle contracts?” From Mackenzie, he received the reply, “You are the man I have been looking for; I have hearts which I observed in patients over a long series of years and now I want someone to examine them.” As part of the histological examination of these hearts, Keith noted “a small condensed area of tissue, just where the cava sank into the auricle.” At the time, Keith observed that “we noted this structure, but attached no functional meaning to it.” Then, late in 1905, Mackenzie asked Keith to look into the state of the purported muscular connection between the atrial and ventricular musculatures, the so-called bundle of His. This structure had been described by His while working in Leipzig in 1893. Keith, however, had been unable to locate the bundle and had written a letter to the Lancet telling of his scepticism. Fortunately, by the time he received the proof from the Lancet, Mackenzie had sent him “a paper by Professor Aschoff, then of Marburg.” Aschoff’s account was “based on a research carried out in his laboratory by Dr. S. Tawara, a Japanese.” As Keith went on to describe, “With Tawara’s description and figures to guide me, I was able in heart after heart to verify the existence of Tawara’s system.” It was no exaggeration for Keith to state, “With the discovery of the conducting system of Tawara, heart research entered a new epoch.” Perhaps the first fruit of this new epoch was the equally significant discovery made by Keith himself. By the summer of 1906, Keith had enlisted the help of a young medical student, Martin Flack, the son of the local grocer and butcher. Together, Keith and Flack studied the hearts of smaller animals, such as the mole. Flack drew Keith’s attention to “a wonderful structure he had discovered in the right auricle of the mole.” The arrangement of this structure immediately reminded Keith of the “small condensed area” seen in the human hearts made available by Mackenzie. Stimulated by this recollection, the pair “at once set to work on the sections we had already made, and found this structure in every one of them” (Figure 1B). Thus was discovered the sinus node! A few years after Keith’s discovery, in 1910, Wybau and Lewis demonstrated that the point of initial cardiac excitation corresponds to the location of the sinus node as revealed by Keith.

Structure of Human Sinus Node

As can be confirmed by studies of the human heart (Figure 2A), the sinus node is indeed “a small condensed area of tissue” located “just where the cava [sinks] into the auricle.” In the human heart, the cells making up the node occupy a subepicardial position adjacent to the terminal crest (crista terminalis), usually being arranged around a prominent nodal

1921
artery (Figure 2B), although the relationship to the artery varies from individual to individual. The nodal cells are set in a matrix of fibrous tissue, with a relatively discrete boundary seen between the margins of the node and the adjacent atrial tissues (Figure 2B). The earliest reconstructions of the node showed it to be a small discrete collection of tissues at the crest of the right atrial appendage, at the junction of the superior caval vein with the right atrium, but this is not typical. In a small proportion of cases, the node can extend across the crest of the right atrial appendage and occupy the interatrial groove. More typically, however, the node is lateral and inferior to the crest. When reconstructed from serial sections, it is found to take the form of a cigar, with a tail of varying dimensions extending down the terminal crest toward the orifice of the inferior caval vein (Figure 2A).

**Structure of Sinus Node in Other Mammals**

The location of the sinus node is different in the hearts of smaller mammals. Nodal cells, instead of being located at the superior cavoatrial junction, occupy the full thickness of the intercaval area adjacent to the terminal crest, as shown by our recent reconstruction of the rabbit sinus node. The reconstruction, shown in Figure 3, reveals the node to be extensive. At its margins, zones of transitional cells, shown in blue in Figure 3, form the junction with the atrial muscle of the terminal crest. In the rat, the node is positioned differently: The bulk of it lies in the superior caval vein, at the crest of the right atrial appendage, and tails of nodal tissue extend down both the terminal crest and the interatrial groove, as occurs in some humans (see above). In the developing heart, the nodal primordium is extensive (Figure 4). In the mouse, as identified by marker genes such as the T-box transcription factor, Tbx3, a continuous tract of primary myocardium, the future nodal tissue, extends from the superior caval vein down the terminal crest (Figure 4, asterisk) to become continuous with the primary myocardium of the atrioventricular (AV) canal destined to form the AV node. This is consistent with the distribution of nodal tissue in the adult rabbit (Figure 3). The continuous tract of primary myocardium in the developing heart is suggestive of an “internodal tract,” such as that proposed by James to provide preferential conduction from the sinus node to the AV node. With the use of standard histological techniques in

the postnatal heart, however, it is not possible to identify any insulated atrial tracts, and much of the primary myocardium loses the histological features of nodal tissue as the embryo matures. Furthermore, in the postnatal heart, preferential conduction from the sinus node to the AV node, as well as into the left atrium, can adequately be explained on the basis of the orderly longitudinal packing of atrial myocytes in prominent muscular bundles, such as the terminal crest and Bachmann’s bundle.

Leading Pacemaking Site

Whereas in smaller mammals, the sinus node extends from the superior caval vein to the inferior caval vein (Figure 3), in the human, the node, as identified by histology, is more restricted and extends only part of the way down the terminal crest (Figure 2A). Functional studies, nonetheless, have suggested that the node in the human may be as extensive as in smaller mammals. As shown in Figure 5, in the human, as in other mammals, although the leading pacemaking site can be next to the superior caval vein, it can also be at any position between the superior and inferior caval veins. In the dog, total ablation of pacemaker activity requires the destruction of a block of tissue extending from the superior caval vein along the terminal crest to the inferior caval vein. It is well known that the position of the leading pacemaking site in the node shifts depending on conditions, such as autonomic nerve stimulation. It has been suggested that there is a hierarchy of pacemakers within the node, and the more superior the position, the faster is the heart rate. Stimulation of the sympathetic nervous system, for example, leads to a superior shift of the leading pacemaking site and an increase in heart rate. The potentially widespread distribution of nodal cells may also be important pathologically because ectopic sites along the terminal crest are known to be responsible for atrial tachycardia. Ablation of the sites abolishes the tachycardias.

Pacemaking Mechanisms

In Figure 6B and 6C, we show the sequence of atrial activation as measured in an experiment and as calculated with the anatomic model of the sinus node shown in Figure 3. The action potential, initiated in the center of the node, propagates via the periphery of the node into the musculature of the terminal crest. In the center of the node, the action potential is slow and small compared with the action potential in the surrounding atrial muscle (Figure 6A). Most importantly, during diastole, whereas in the atrial muscle there is a stable resting potential, in the node the membrane is more depolarized, and there is a pacemaker potential, ie, a further time-dependent depolarization (Figure 6A). This pacemaker potential is responsible for pacemaking because, on reaching threshold, it initiates the action potential. Electric activity varies throughout the node: In the periphery, the action potential is faster and larger, and, curiously, the intrinsic pacemaker activity is faster than in the center (Figure 6D). Early attempts to understand the mechanisms underlying pacemaking were made in the 1970s, and efforts to understand it continue today. It is a controversial topic, perhaps because there is no one dominating mechanism but rather many contributory mechanisms. The depolarization during the pacemaker potential is the result of inward current, although it is facilitated by the decay of outward current (Figure 7).

Inward Currents

In the center of the node, the action potential upstroke is slow (Figure 6A) because the myocytes express little or no Na+ current, $I_{Na}$. It is the L-type Ca2+ current, $I_{Ca,L}$, that is...
principally responsible for the upstroke. $I_{\text{Na}}$, nonetheless, is important. In the rabbit, evidence suggests that, although $I_{\text{Na}}$ is absent in the center of the node, it is present in the periphery. Block of $I_{\text{Na}}$ by tetrodotoxin (TTX) slows pacemaking in the periphery. $I_{\text{Na}}$ may be more important in the mouse sinus node: Two components of $I_{\text{Na}}$ have been recorded, a novel Na$^+$ current that is blocked by nanomolar concentrations of TTX and the classic cardiac Na$^+$ current that is blocked by micromolar concentrations of TTX. Block of both components slows pacemaking by approximately one third (Figure 7E) and also increases the sinus node conduction time, ie, the time taken for the action potential to propagate out of the node. It is possible, therefore, that $I_{\text{Na}}$ plays 2 roles in the node: in pacemaking, especially in the mouse, and in action potential conduction (if the node is to drive the surrounding atrial muscle, it must be able to provide sufficient inward current to stimulate the atrial muscle, and this may be the function of $I_{\text{Na}}$, especially in the periphery). Block of $I_{\text{Ca,L}}$ abolishes the action potential in the center of the node (Figure 7A) because it is responsible for the action potential upstroke. The T-type Ca$^{2+}$ current ($I_{\text{Ca,T}}$) is also involved in pacemaking; it is possibly involved in the second half of the pacemaker potential. When $I_{\text{Ca,T}}$ is blocked by Ni$^{2+}$, spontaneous rate slows by $\sim 13\%$ in rabbit nodal cells (Figure 7C). The funny current, $I_{\text{f}}$, is also important. When $I_{\text{f}}$ is blocked, spontaneous rate slows by $\sim 14\%$ in the rabbit sinus node (Figure 7B). Procoralan, or ivabradine, a blocker of $I_{\text{f}}$, is now being marketed as the first pure heart rate–lowering cardiac agent.

The Na$^+$-Ca$^{2+}$ exchanger is responsible for Ca$^{2+}$ extrusion from cardiac myocytes (Figure 7D). The exchanger is electrogenic and generates an inward current ($I_{\text{NaCa}}$) during Ca$^{2+}$ extrusion (Figure 7D). The total charge carried by inward $I_{\text{NaCa}}$ is substantial: approximately half that carried by $I_{\text{Ca,T}}$ and $I_{\text{Ca,L}}$, if the myocyte is to be in Ca$^{2+}$ balance. If the extrusion of Ca$^{2+}$ occurs in diastole, inward $I_{\text{NaCa}}$ may make an important contribution to pacemaking. The source of Ca$^{2+}$ that drives its extrusion via the exchanger is release from the sarcoplasmic reticulum (SR). All investigators agree that effective block of this release by ryanodine slows pacemaking (Figure 7F). There is disagreement, nonetheless, over detail: whether Ca$^{2+}$ release from the SR speeds pacemaking simply by activating the exchanger or by acting on other ionic currents as well; whether complete block of the exchanger stops pacemaking or only slows it by $\sim 20\%$; Li$^+$ cannot substitute for Na$^+$ in Na$^+$-Ca$^{2+}$ exchange, and abolition of inward $I_{\text{NaCa}}$ by substitution of extracellular Na$^+$ by Li$^+$ also results in a slowing of pacemaking. Recently, Vinogradova et al argued that spontaneous release of Ca$^{2+}$ from the SR, which drives pacemaking, occurs because the basal level of cAMP in the node is high. A heterozygous ankyrin-B knockout mouse shows both bradycardia and sinus dysrhythmia. Ankyrin-B is a membrane adaptor protein involved in the cellular organization of the Na$^+$ pump, the Na$^+$-Ca$^{2+}$ exchanger, and the IP$_3$ receptor. Myocytes from the heterozygous ankyrin-B knockout mouse show disturbed intracellular Ca$^{2+}$ handling. Could the bradycardia be the result of a change in $I_{\text{NaCa}}$?

**Outward Currents**

The background inward rectifier K$^+$ current, $I_{\text{K,I}}$, is largely responsible for the stable resting potential in the working
myocardium. Despite the presence of $I_{K1}$, Purkinje fibers show $I_f$-dependent pacemaking, but the pacemaking is slow and not robust. Perhaps the most important factor responsible for the rapid and robust pacemaking of the node is the absence of $I_{K1}$ within the node. During the action potential in the node, there is an activation of the rapid and slow delayed rectifier $K^+$ currents, $I_{K1, r}$ and $I_{K1, s}$; this helps to bring about repolarization and determines the maximum diastolic potential. During diastole, $I_{K1, r}$ and $I_{K1, s}$ decay slowly, facilitating the pacemaker potential by “uncovering” inward current. This is known as the $K_{11001}$ decay hypothesis. In *Drosophila*, a background $K^+$ channel (2-pore $K^+$ channel, ORK1) has been shown to affect cardiac pacemaking.

**Ion Channels**

Ion channel expression in the sinus node has been studied at the mRNA and protein levels and, as expected, is radically different from that in the working myocardium.

**Na$^+$ Channels**

The cardiac Na$^+$ channel, Na,1.5, encoded by the SCN5A gene, is responsible for the classic cardiac Na$^+$ current that is blocked by micromolar concentrations of TTX. Consistent with the electrophysiology, in both the human (Figure 8A) and other mammals (Figure 9), Na,1.5 is present in the atrial muscle and the periphery of the node but absent from the center. During the action potential in the node, there is an activation of the rapid and slow delayed rectifier $K^+$ currents, $I_{K1, r}$ and $I_{K1, s}$; this helps to bring about repolarization and determines the maximum diastolic potential. During diastole, $I_{K1, r}$ and $I_{K1, s}$ decay slowly, facilitating the pacemaker potential by “uncovering” inward current. This is known as the $K^+$ decay hypothesis. In *Drosophila*, a background $K^+$ channel (2-pore $K^+$ channel, ORK1) has been shown to affect cardiac pacemaking.

**Ca$^{2+}$ Channels**

In the working myocardium, Ca,1.2 ($\alpha_{Ca1}$) is the principal isoform responsible for $I_{Ca1}$, but in the node, Ca,1.3 ($\alpha_{Ca1}$) may be the principal isoform. Ca,1.3 has a more negative threshold potential and may be more appropriate for pace-

making. In the mouse, knockout of Ca.1.3 causes bradycardia and sinus dysrhythmia, and this is linked to abolition of the major component of \( I_{\text{Ca,L}} \) activating at negative voltages.\(^{51,52} \)

Cav3.1 and Cav3.2 channels are responsible for \( I_{\text{Ca,T}} \) in heart. In the mouse, Cav3.1 mRNA is \( \approx30 \) times more abundant in the node than in the atrial muscle. Cav3.2 mRNA, although less abundant, is also more abundant in the node than in the atrial muscle.\(^{53} \) In the mouse, knockout of Cav3.1 abolishes \( I_{\text{Ca,T}} \) in nodal cells, causes a bradycardia in vivo, slows the intrinsic heart rate in vivo, prolongs the sinus node recovery time, and slows pacemaking in vitro.\(^{54} \)

HCN Channels

HCN channels (HCN1, HCN2, and HCN4) are responsible for \( I_{\text{f}} \) in heart. HCNs are highly expressed in the node in both the human (Figure 8B) and other mammals (Figure 9).\(^{12} \) The dominant HCN transcript is HCN4.\(^{55,56} \) In the rabbit sinus node, HCN4 mRNA accounts for approximately four fifths of total HCN mRNA, HCN1 mRNA accounts for approximately one fifth, and HCN2 mRNA accounts for only 1%.\(^{55} \) In the mouse, knockout of the HCN2 gene results in a reduction of \( \approx30\% \) in \( I_{\text{f}} \) in nodal cells.\(^{57} \)

In vivo there is no significant bradycardia, but there is sinus dysrhythmia.\(^{57} \) HCN4 knockout mice die before birth, but the embryos exhibit a severe bradycardia and an 85% decrease in cardiac \( I_{\text{f}} \).\(^{58} \)

\( K^+ \) Channels

In the rabbit, at least, there is a slowly recovering transient outward current, \( I_{\text{so}} \) in the atrial muscle and a rapidly recovering one in the node.\(^{59} \) Consistent with this, there is a switch from K.1.4 in the atrial muscle to K.4.2 in the node.\(^{50} \) K.1.5 is responsible for ultrarapid delayed rectifier \( K^+ \) current, an important repolarizing current in the atrium. In the guinea pig, it is expressed in the node as well as the atrium.\(^{60} \) Consistent with the electrophysiology, both ERG (responsible for \( I_{\text{Ku}} \)) and K.LQT1 (responsible for \( I_{\text{Ks}} \)) mRNA are expressed in the rabbit sinus node, and expression is higher than in the atrial muscle.\(^{50} \) K.2 channels, responsible for \( I_{\text{Kr}} \), are not expected to be expressed in the node. Possible evidence of such a restriction of expression comes from a study of a transgenic mouse overexpressing K.2.1 (Figure 10A).\(^{61} \) Figure 8C shows that, in the human, K.2.1 (this time the native channel) is indeed not expressed in the node, although it is expressed in atrial muscle. Evidence suggests that, whereas the abundance of K.3.1 and K.3.4, responsible for acetylcholine-activated \( K^+ \) current, \( I_{\text{K,AC}} \), is equal in the node and atrial muscle, the abundance of Kir6.2 and SUR2A, responsible for ATP-sensitive \( K^+ \) current, \( I_{\text{K,ATP}} \), may be reduced in the node compared with in the atrial muscle.\(^{50,62} \)

Gap Junctions

Whereas electric coupling in the working myocardium is strong, facilitating rapid conduction of the action potential, electric coupling within the sinus node is poor, and consequently conduction is slow.\(^{24,63} \) This is important functionally because it protects the pacemaking tissue from the hyperpolarizing influence of the surrounding atrial muscle.\(^{64} \) If electric coupling was uniformly poor throughout the node, the node would be unable to drive atrial muscle. It has been postulated, therefore, that there should be strong electric coupling at the periphery of the node.\(^{64} \) Gap junction channels, composed of connexins, are responsible for electric coupling between myocytes. In the atrial muscle, the strong electric coupling is the result of the abundant expression of Cx43 and perhaps Cx40, which form medium and large conductance channels.\(^{63} \) In the center of the node, electric coupling is weak because Cx43 and Cx40 are either absent or poorly expressed (eg, Figure 10B).\(^{61,63} \) Cx45, which forms small conductance channels, is expressed in the center of the node instead.\(^{63} \) Recently, Cx30.2 has been found to be expressed abundantly in the mouse conduction system, whereas it is weakly expressed in the working myocardium.\(^{65} \) Cx30.2 forms small conductance homomeric channels and small conductance heteromeric channels with Cx43 and Cx40.\(^{65} \) There is evidence that electric coupling is stronger in the periphery of the node: In the rabbit, 3 connexins (Cx40, Cx45, and Cx43) are expressed in the periphery.\(^{63} \) In various species, including humans, interdigitations of atrial and nodal cells in the periphery of the node have been reported.\(^{63} \) It has been suggested on theoretical grounds that these interdigita-
tions permit the node to drive the surrounding atrial muscle and at the same time to be protected from the hyperpolarizing influence of the atrial muscle. In Cx40 knockout mice, there is evidence of bradycardia, sinus node exit and entry block, and a prolongation of the sinus node conduction time.

**New Insights**

**Familial Sick Sinus Syndrome**

As explained above and as summarized in the Table, the knockout of various ion channel and gap junction subunits in transgenic mice has been shown to result in a sick sinus syndrome phenotype, with bradycardia, sinus dysrhythmia, and sinus node exit block. These studies raise the possibility that sick sinus syndrome as seen clinically is related to problems with ion channels and gap junctions. In the case of familial sick sinus syndrome, at least, the disease has been shown to be the result of mutations in ion channels (Table). Various families have been identified with sick sinus syndrome linked to mutations in Nav1.5 (Figure 11A). This is paradoxical because Nav1.5 is absent from the center of the node (Figure 8A). The dysfunction must be the result of impaired function of Nav1.5 at the periphery of the node (Figure 9). In addition, in patients, sinus bradycardia/sick sinus syndrome has also been linked to mutations in HCN4 and ankyrin-B.

**Sick Sinus Syndrome and Aging**

Because the syndrome is age dependent, it is possible that the disease can be no more than an exaggeration of the normal aging process. The function of the node is known to decline during aging in both humans and other mammals. This is manifested as a decrease in the intrinsic heart rate and an increase in the sinus node conduction time. The age-dependent changes in the node could be the result of changes in ion channels and gap junctions. It has been argued that the presence of Na,1.5 (Figure 9) and I_{Na} in the periphery of the node is important for the node to be able to drive the surrounding atrial muscle. An age-dependent slowing of the action potential upstroke in the periphery of the rabbit sinus node is evidence of a loss of I_{Na} from the periphery during

---

*References 43, 47, 48, 51, 52, 54, 57, 58, 67–75.*
aging, and this could help to explain the deterioration in nodal function, ie, the increase in sinus node conduction time and sinus node exit block.\textsuperscript{78} There is an increase in action potential duration in the rabbit and cat sinus node during aging;\textsuperscript{77} is this the result of an age-dependent decrease in $K_v1.5$ observed in the rat sinus node?\textsuperscript{79} In the guinea pig, there is a decrease in the expression of Cx43 in the region of the node during aging, with an $\approx 14$-fold increase in the area of nodal tissue without Cx43.\textsuperscript{80} Like the suggested loss of $I_{Na}$ from the node during aging, this could help to explain the increase in the sinus node conduction time and occurrence of sinus node exit block with aging.\textsuperscript{80}

**Remodeling of the Sinus Node in Heart Failure and Atrial Fibrillation**

In the United States, up to 5 million patients experience congestive heart failure, and sudden cardiac death is a significant problem in this population.\textsuperscript{81} Bradyarrhythmias account for almost half of the sudden deaths in the hospital.\textsuperscript{81} It is now known that heart failure results in significant remodeling of the node.\textsuperscript{81,82} In the human, dog, and rabbit, there is a decrease in the intrinsic heart rate during heart failure.\textsuperscript{81,83--85} Sanders et al\textsuperscript{81} demonstrated that, in patients with congestive heart failure as well as a decrease in the intrinsic heart rate, there is an increase in the corrected sinus node recovery time, a caudal shift of the leading pacemaker site, fractionated electrograms or double potentials along the terminal crest, a decrease in the amplitude of the electrograms along the terminal crest, and abnormal propagation of the action potential from the node. Changes in sensitivity of the node to acetylcholine and vagal stimulation have been observed in heart failure in the rabbit and dog.\textsuperscript{82,84} With heart failure, in the rabbit, block of $I_f$ by zatebradine causes a
smaller decrease in the heart rate, and the decrease in sinus node pacemaking has been attributed to a decrease in \( I_{K1} \).

With heart failure, in the dog, a decrease in HCN2 and HCN4 mRNA and protein by \( 80\% \) is observed in the node. Atrial fibrillation (AF) is one of the most common cardiac arrhythmias and in the atria is well known to result in an electrophysiological remodeling. Clinical studies have shown that sick sinus syndrome is frequently associated with AF and atrial flutter, the “bradyarrhythmia-tachyarrhythmia syndrome.” Clinical studies have shown that AF is associated with significant damage to the node and the nodal artery. In the dog, rapid atrial pacing at 400 bpm for 16 days, as well as chronic AF, results in nodal dysfunction: prolongation of the sinus node recovery time and decreases in the intrinsic and maximal heart rates. Comparable data have been reported in the human. For example, symptomatic prolonged sinus pauses on termination of AF are an indication for pacemaker implantation. In these patients, however, after AF ablation, there is a significant improvement in nodal function (increase in heart rate, maximal heart rate and heart rate range, and decrease in corrected sinus node recovery time). This corresponds to a recovery of the node from remodeling during AF. In patients, termination of chronic atrial flutter by ablation also leads to recovery of nodal function. In the human, rapid atrial pacing for only 10 to 15 minutes alters nodal function.

Future Directions

Sick sinus syndrome is a collection of conditions with multiple causes. Although degenerative fibrosis may be an important cause, it is clear that ion channels underlie the familial disease, as well as the variants related to heart failure and AF. They may also be important in the aging-related syndrome. If this is the case, manipulation of the expression of the genes regulating the ion channels in the node could be a powerful therapeutic tool. Recently, there has been much interest in generating a “biopacemaker” by manipulation of ion channel genes in the working myocardium. To date, attention has focused on either knocking out K\(_{2.1}\), and thus \( I_{K1} \), because K\(_{2.1}\) is not expressed in the node (eg, Figure 8C), or expressing an HCN channel because HCNs are abundantly expressed in the node (eg, Figure 8B). An example of the conversion of a ventricular cell into a biopacemaker (by knocking out K\(_{2.1}\)) is shown in Figure 11C. There are, however, many differences in the expression of ion channels between the sinus node and working mycardium, as we have explained above, and perhaps \( >1 \) ion channel has to be manipulated to make an effective and robust new pacemaker. An alternative and potentially more attractive possibility could be the transfer of an appropriate gene into the node itself to correct sick sinus syndrome.

Disclosures

Dr Dobrzynski has received a research grant from Medtronic. The other authors report no conflicts of interest.
