Epidemiology and Prevention

Ideal Cardiovascular Health and Mortality From All Causes and Diseases of the Circulatory System Among Adults in the United States

Earl S. Ford, MD, MPH; Kurt J. Greenlund, PhD; Yuling Hong, MD, PhD

Background—Recently, the American Heart Association developed a set of 7 ideal health metrics that will be used to measure progress toward their 2020 goals for cardiovascular health. The objective of the present study was to examine how well these metrics predicted mortality from all causes and diseases of the circulatory system in a national sample of adults in the United States.

Methods and Results—We used data from 7622 adults ≥20 years of age who participated in the National Health and Nutrition Examination Survey from 1999 to 2002 and whose mortality through 2006 was determined via linkage to the National Death Index. For the dietary and glycemic metrics, we used alternative measures. During a median follow-up of 5.8 years, 532 deaths (186 deaths resulting from diseases of the circulatory system) occurred. About 1.5% of participants met none of the 7 ideal cardiovascular health metrics, and 1.1% of participants met all 7 metrics. The number of ideal metrics was significantly and inversely related to mortality from all causes and diseases of the circulatory system. Compared with participants who met none of the ideal metrics, those meeting 5 metrics had a reduction of 78% (adjusted hazard ratio, 0.22; 95% confidence interval, 0.10–0.50) in the risk for all-cause mortality and 88% (adjusted hazard ratio, 0.12; 95% confidence interval, 0.03–0.57) in the risk for mortality from diseases of the circulatory system.

Conclusion—The number of ideal cardiovascular health metrics is a strong predictor of mortality from all causes and diseases of the circulatory system. (Circulation. 2012;125:987-995.)

Key Words: cardiovascular diseases ■ epidemiology ■ mortality ■ population ■ prevention ■ risk factors

Despite an impressive decline in the mortality rate from coronary heart disease and stroke since the 1960s, preliminary estimates for 2010 show that 595 444 people died of diseases of the heart, which remains the leading cause of death in the United States, and 129 180 died of cerebrovascular diseases.1 Consequently, more progress in reducing the mortality rate remains to be achieved. Reducing the mortality rate can be realized by lowering the incidence of cardiovascular disease, lowering the case-fatality rate of cardiovascular disease, or their combination.

Editorial see p 973
Clinical Perspective on p 995

In the recently released American Heart Association’s “Strategic Impact Goal Through 2020 and Beyond,”2 the AHA charted a new course by focusing on improving cardiovascular health in addition to decreasing cardiovascular disease mortality. The AHA developed 7 metrics that address cardiovascular health and created 3 states for each metric that reflected poor, intermediate, and ideal health. These metrics draw on the extensive body of epidemiological investigations that identified critical risk factors for cardiovascular disease and clinical trials that confirmed that lowering the level of some of these risk factors reduced the morbidity and mortality from cardiovascular disease. Furthermore, the AHA 2020 goals align more closely with the concept of primordial prevention3 and grew out of investigations that championed primordial prevention.4,5 Several studies have variably defined a low cardiovascular risk profile based on different risk factors and behaviors.6–10 However, at present, little is known about how well the new AHA 2020 goals predict the incidence and mortality from cardiovascular disease.11 Therefore, the objective of the present study was to examine the relationship between the AHA 2020 goals and mortality from all causes and diseases of the circulatory system in a recent cohort of US adults.

Methods

We used the public data files for the 2006 follow-up of participants of the 1999 to 2000 and 2001 to 2002 cycles of the National Health and Nutrition Examination Survey (NHANES). The samples in 1999

987
to 2000 and 2001 to 2002 were selected by use of a multistage, stratified sampling design and constitute representative samples of the noninstitutionalized civilian US population. Participants were interviewed at home and invited for a clinical examination. Details about the NHANES and its methods have been published. The study received approval from the National Center for Health Statistics Research Ethics Review Board, and participants were asked to sign an informed consent form.

The mortality status of participants ≥20 years of age through 2006 was determined from the National Death Index. Participants who were not deemed to have died as of December 31, 2006, were considered to be alive. The *International Classification of Diseases*, 10th revision, codes 100 to 199 were used to identify deaths from diseases of the circulatory system.

The AHA 2020 goals include the following 7 behaviors and risk factors: smoking status, body mass index, physical activity, healthy dietary score, total cholesterol, blood pressure, and fasting plasma glucose. Participants who had smoked 100 cigarettes during their lifetime and were still currently smoking were defined as showing evidence of poor health. Former smokers who had quit within the previous 12 months were defined as showing evidence of intermediate health. Former smokers who had quit for >12 months or participants who had never smoked were defined as showing evidence of ideal health. Body mass index was calculated from measured weight and height. Participants with a body mass index of ≥30, 25 to <30, and <25 kg/m² had poor health, intermediate health, and ideal health, respectively. Participants were asked about the frequency and duration of participation in moderate and vigorous physical activity during the past 30 days. The weekly frequency of bouts of physical activity was calculated by multiplying the number of such bouts during the 30-day period by a factor of 7/30. For each participant, the weekly number of minutes of moderate activity (weekly frequency multiplied by the average duration for each bout) and the weekly number of minutes of vigorous activity (weekly frequency multiplied by the average duration for each bout multiplied by 2) were summed. Ideal health, intermediate health, and poor health were defined as ≥150, 1 to 149, and 0 minutes of moderate or vigorous activity per week, respectively.

In lieu of the AHA specific dietary criteria, we used the Healthy Eating Index (HEI) score as our healthy dietary score. The HEI includes 3 of the 5 primary criteria included in the AHA healthy dietary score: fruits and vegetables, whole grains, and sodium. Not included are sugar-sweetened beverages and fish consumption. Participants with an HEI score <50 were assigned to poor health; those with a score of >50 to <80 were assigned to intermediate health; and those with a score of ≥81 were assigned to ideal health. The index was determined from dietary information collected by a single 24-hour recall administered in person to participants attending the medical examination.

Serum total cholesterol and high-density lipoprotein cholesterol were measured enzymatically on a Hitachi 717 Analyzer or a Hitachi 912 Analyzer (Roche Diagnostics, Indianapolis, IN). Ideal health, intermediate health, and poor health were defined as <200 mg/dL, 200 to 239 mg/dL or treated to goal, and ≥240 mg/dL, respectively. Up to 4 attempts were made to measure blood pressure. The average of the last 2 measurements of blood pressure for participants who had 3 or 4 measurements, the last measurement for participants with only 2 measurements, and the only measurement for participants who had 1 measurement were used. Current use of antihypertensive medications was based on self-report. Ideal health, intermediate health, and poor health were defined as systolic blood pressure <120 mm Hg and diastolic blood pressure <80 mm Hg, systolic blood pressure of 120 to 139 mm Hg and diastolic blood pressure of 80 to 89 mm Hg or treated to goal, and systolic blood pressure ≥140 mm Hg and diastolic blood pressure ≥90 mm Hg, respectively.

Although the AHA relied on fasting plasma glucose to determine hyperglycemia, we used hemoglobin A1c (HbA1c) concentrations for 2 reasons. First, recent (2010) recommendations from the American Diabetes Association allow the use of HbA1c to diagnose diabetes mellitus. Second, a sizeable percentage of participants in NHANES who have an examination are not fasting. Therefore, to maximize our sample size, we opted for concentration of HbA1c, which is not subject to fasting conditions. Participants with an HbA1c ≥6.5% had poor health; those with a concentration of 5.7 to <6.5% had intermediate health; and those with a concentration <5.7% had ideal health. Participants who reported being treated with insulin or oral medications to lower blood glucose and had a concentration <6.5% were deemed to have intermediate health.

We included several covariates in our analyses: age, sex, race or ethnicity (white, black, Mexican American, other), educational status (less than high school, high school graduate, General Educational Development or equivalent, more than school), alcohol use, self-
reported health status, health insurance, history of cardiovascular disease, and history of cancer. We calculated alcohol use from several questions regarding the use of alcohol during a participant’s lifetime and 12-month period and recent use. Men who consumed an average of 2 drinks per day and women who consumed an average of 1 drink per day were considered moderate drinkers, and men who consumed an average of 2 drinks per day and women who consumed an average of >1 drink per day were considered excessive drinkers. Self-reported health status was determined from the question, “Would you say your health in general is excellent, very good, good, fair, or poor?” Health insurance coverage (yes/no) was derived from the question, “Are you covered by health insurance or some other kind of healthcare plan?” Participants who reported ever being told by a doctor or other health professional that they had congestive heart failure, coronary heart disease, angina pectoris, heart attack, or stroke were considered to have a history of cardiovascular disease.

Our analyses were limited to participants who were ≥20 years of age. We calculated mortality rates per 1000 person-years of follow-up. Adjustment for age or age and sex was performed by use of the direct method with the year 2000 US population. Differences in age- and sex-adjusted proportions were examined with χ² tests. Pearson correlations adjusted for age and sex between the ranks of continuous variables used to formulate the health metrics were calculated. Risk estimates for mortality were calculated by the use of Cox proportional hazards regression analysis for the individual and number of 2020 cardiovascular health goals. In these analyses, we adjusted for age (continuous), sex, race or ethnicity (white, black, Mexican American, other), educational attainment (less than high school, high school graduate or equivalent, and beyond high school), alcohol use (excessive alcohol use yes/no), self-reported health status (fair or poor health; good, very good, or excellent health), health insurance coverage (yes/no), and histories of cardiovascular disease (yes/no) and cancer (yes/no). Proportionality assumptions were examined with Schoenfeld residuals and were found to be met. Estimates were calculated with SAS and SUDAAN, the latter to account for the complex sampling design of the survey.

### Results

Of the 9471 participants ≥20 years of age who had an examination, 10 were ineligible for the follow-up study and 8005 had sufficient information for the cardiovascular health metrics. Additional exclusions for incomplete information of other study variables reduced the sample size to 7622. The sample included 3635 men, 3987 women, 3857 whites, 1329

</table>

blacks, 1814 Mexican Americans, and 622 of another race or ethnicity. The median age was 43 years.

The age- and sex-adjusted prevalence of ideal health for the individual health factors ranged from 10.9% for the HEI dietary score to 81.3% for HbA₁c (Table 1). Without adjustment, 1.5% of participants had no ideal health criteria, 8.4% had 1, 19.9% had 2, 27.4% had 3, 22.1% had 4, 14.0% had 5, 5.5% had 6, and 1.1% had 7 (after adjustment for age and sex: 1.5%, 8.6%, 20.3%, 27.5%, 21.9%, 13.8%, 5.4%, and 1.0%, respectively). The interrelationships between the dichotomized health metrics and correlations for continuous variables are shown in Tables 2 and 3.

During a median follow-up of 5.8 years, 532 deaths (186 deaths resulting from diseases of the circulatory system) were recorded among the 7622 participants. Smoking status, dietary score, HbA₁c, physical activity, and blood pressure were significantly associated with all-cause mortality (Table 4). In the maximally adjusted model, only smoking status, physical activity, HEI score, blood pressure, and HbA₁c, retained their statistical significance. Five metrics (smoking status, physical activity, HEI score, blood pressure, and HbA₁c) showed evidence of a graded response, indicating that the intermediate health categories for these metrics were associated with reduced all-cause mortality. With the exception of blood pressure, the hazard ratios for mortality from diseases of the circulatory system generally were aligned with those for all-cause mortality, although the confidence limits included unity.

Four of the 7 dichotomized cardiovascular health metrics (ideal health versus intermediate or poor) were significantly associated with all-cause mortality (the Figure, A). Ranked according to the magnitude of the hazard ratio for all-cause mortality were ideal smoking status, HbA₁c, and dietary score, and physical activity. For mortality from diseases of the circulatory system, ideal health for blood pressure proved to be a particularly strong determinant. Furthermore, dietary score and HbA₁c were also significantly associated with this outcome. We also reid the above models after revising the outcome variable by comparing ideal and intermediate health with poor health (the Figure, B). The resulting magnitude and rank order of the hazard ratios showed some differences from those of the models in part A of the Figure.

When the dichotomized cardiovascular health metrics were summed, a strong inverse relationship was present between the number of ideal health metrics and mortality from all causes or diseases of the circulatory system (Table 5). Because so few deaths occurred among participants with 6 or 7 ideal health metrics, we grouped participants with 5, 6, or 7 ideal health metrics into 1 category. Compared with participants with no ideal health metrics, those with ≥5 had reduced all-cause mortality (adjusted hazard ratio, 0.22; 95% confidence interval [CI], 0.10–0.50) and mortality from diseases of the circulatory system (adjusted hazard ratio, 0.12; 95% CI, 0.03–0.57). When participants who died during the first year of follow-up were excluded from the analyses (481 deaths, 7571 at risk), a strong reduction in risk with increasing number of ideal health metrics remained evident (adjusted hazard ratios for participants with 1, 2, 3, 4, and ≥5 ideal health metrics are 0.68 [95% CI, 0.32–1.45], 0.69 [95% CI, 0.31–1.52], 0.58 [95% CI, 0.24–1.38], 0.49 [95% CI, 0.19–1.27], and 0.22 [95% CI, 0.08–0.62]). Furthermore, after the exclusion of participants with self-reported cardiovascular disease from the analyses, the hazard ratios for participants with ≥5 ideal health metrics were similar to the hazard ratios for the entire analytic sample of 7622 participants.

We also created a score out of the 7 cardiovascular health metrics ranging from 0 to 14 by assigning a value of 0 for poor health, 1 for intermediate health, and 2 for ideal health for each metric. The maximally adjusted hazard ratio per unit score was 0.86 (95% CI, 0.81–0.91) for all-cause mortality and 0.83 (95% CI, 0.76–0.91) for mortality resulting from diseases of the circulatory system.

Discussion

Using a recent national sample of US adults, we show that the number of ideal cardiovascular health metrics was strongly...
and inversely related to mortality from all causes and diseases of the circulatory system. These data, which are consistent with the results from a recent prospective study, suggest that attainment of the AHA 2020 goals could result in substantial reductions in mortality.

Since the 1960s, mortality from coronary heart disease has enjoyed a more or less sustained decrease. The early period of this drop was likely governed primarily by reductions in the prevalence of smoking, mean concentration of total cholesterol, and blood pressure. The introduction of the coronary care unit during the 1960s and its subsequent expansion also saved lives. The development of ever more sophisticated medical and surgical treatments in ensuing decades contributed further to reducing the mortality rate from coronary heart disease. Between 1980 and 2000, treatments accounted for 47% and reductions in risk factors for 44% of the deaths from coronary heart disease that were prevented or postponed in the United States. Models consistently show that enormous reductions in the mortality from coronary heart disease are achievable with meaningful reductions in risk factors. Thus, the development of the AHA 2020 goals that emphasize cardiovascular health represents

The National Death Index was used to ascertain mortality through 2006.
an important evolution from disease management to health promotion.

Controlling for confounding constitutes a major challenge in observational studies. To examine the impact of various possible confounders on our risk estimates, we presented several proportional hazards models that contained different sets of covariates. We included self-reported health and prevalent chronic disease as possible confounders because these factors are related to mortality and to the AHA cardiovascular health metrics. Conceivably, these factors could also form part of the causal pathways between the AHA metrics and mortality, in which case the model was overadjusted and the benefits attributable to the metrics were underestimated. However, a comparison of models with and without these factors shows that self-reported health and prevalent chronic disease did not materially affect the hazard ratios. Similar considerations apply to the model that adds all the AHA metrics.

Our analyses using the NHANES 1999 to 2002 data show that only a small percentage of US adults met ideal criteria for all 7 cardiovascular health metrics, a result that is disappointing but perhaps not surprising. One consequence of the very small percentage of participants in the extremes of the distribution is that large cohorts with large numbers of deaths are needed to form stable and accurate estimates of the risk for mortality among those with 6 or 7 ideal health metrics. Most adults met 2, 3, or 4 ideal health metrics, all of which are associated with a substantial reduction in mortality compared with participants with no ideal health metric. The challenge for clinical and public health professionals is to keep moving the distribution of the number of health metrics in the desired direction. In this regard, a number of major
efforts are underway. An example of a clinical program is the AHA’s The Guideline Advantage, jointly managed by the American Cancer Society, American Diabetes Association, and AHA.23 An example of a recent major public health initiative launched by the US Department of Health and Human Services is the Communities Putting Prevention to Work initiative, which funded 50 communities with the goal of reducing tobacco use, increasing physical activity, improving nutrition, and reducing obesity.24 In addition to continued efforts to promote healthy lifestyles, public health programs will be of value to clinicians in optimizing the cardiovascular health of their patients.

Five of the 7 metrics (current smoking, physical activity, healthy diet score, blood pressure, and HbA1c) showed a gradient in risk, suggesting that health gains are feasible when adults move from poor to intermediate health and when they move from intermediate to ideal health for most health metrics. Future studies comparing the gain in health benefits associated with a change from poor to intermediate health with the gain associated with a change from intermediate to ideal health for each metric may yield helpful insights that will be of value to clinicians in optimizing the cardiovascular health of their patients.

Not all of the individual metrics contributed to the reduction in risk; body mass index and total cholesterol status were not significantly related to mortality from all causes. The reasons for these findings are not clear. Of note, a previous analysis of the mortality experience by NHANES III participants found a weak relationship between body mass index and total cholesterol status were not significantly related to mortality from all causes. The reasons for these findings are not clear. associations for body mass index or other measures of adiposity for coronary heart disease mortality during up to 14 years of follow-up but found positive associations after 14 years of follow-up, suggesting that the effects of adiposity may not become apparent for some time. A recent meta-analysis found that anthropometric measures such as body mass index did not improve risk prediction for cardiovascular disease once traditional cardiovascular risk factors were considered. From a public health perspective, the prevention and control of excess weight represents a valuable public health goal because, in addition to other considerations, excess weight causes dyslipidemia, high blood pressure, and hyperglycemia.

Hypercholesterolemia is considered 1 of the 3 cardinal risk factors for coronary heart disease and has been shown to be a risk factor for all-cause mortality. Consequently, the poor prediction by this risk factor in the present study was unexpected. The use of cholesterol-lowering medications, particularly in the form of statins, has been increasing rapidly in the United States, and some of the non–cholesterol-lowering effects of statin use may have played a role in our findings. Furthermore, the use of cholesterol-lowering medications among the participants with untreated hypercholesterolemia at baseline likely increased, which may have negated some of the adverse effects suggested by elevated baseline concentrations. Alternatively, the lack of a significant association may have represented a chance occurrence. It is also possible that a significant association may emerge with longer follow-up of the cohort.

Our results should be considered in light of several limitations. First, the follow-up of our cohort was of limited duration. Consequently, the number of deaths, even at >500, posed a major challenge in estimating the risks in the extremes of the distribution of the number of ideal health metrics. Thus, collapsing some categories for some analyses was necessary. Furthermore, the limited number of deaths also led us not to undertake stratified analyses by various demographic or other factors. Second, we had only a single measurement for all the health metrics; thus, were unable to account for changes in these metrics that may have occurred during the course of the follow-up period. Finally, as noted before, we did not adhere perfectly to all of the AHA 2020 health metrics for practical reasons.

Other studies are needed to examine the relationships between the AHA 2020 goals and the incidence and mortality of cardiovascular disease. Examining these relationships in historical and in more current cohorts will provide important feedback about the choice of metrics and the selected definitions for poor, intermediate, and ideal health.

CLINICAL PERSPECTIVE

In 2010, the American Heart Association presented a set of 7 metrics that were designed to promote cardiovascular health: smoking status, body mass index, physical activity, healthy dietary score, total cholesterol, blood pressure, and fasting plasma glucose. For each metric, 3 levels of health were defined (poor, intermediate, and ideal health). The state of ideal health for each metric emphasizes the concept of primordial prevention. Using data from a nationally representative cohort of US adults, we found that about half of adults had 3 or 4 ideal health metrics (only ~1% met the ideal health criteria for all 7 metrics). Furthermore, we observed a strong dose-response relationship between the number of ideal health metrics and mortality from all causes and diseases of the circulatory system. Clinicians can reduce cardiovascular morbidity and mortality in their patient populations not only by helping their patients maximize the number of attained ideal cardiovascular health metrics but also by helping patients with poor health for some metrics transition to intermediate health. Optimizing cardiovascular health involves addressing key lifestyle behaviors of smoking, diet, and physical activity. Besides the resources in their practices, clinicians can opt to draw on available institutional, clinical, and community resources. An implication of the AHA goals and our findings is that the cardiovascular health of patients should be monitored from an early age. Clinicians should strive to maximize the numbers of patients with hypercholesterolemia, hypertension, and hyperglycemia who require pharmaceutical management who are on treatment and under control.
Ideal Cardiovascular Health and Mortality From All Causes and Diseases of the Circulatory System Among Adults in the United States
