Ischemic mitral regurgitation (MR) is common and increases heart failure and mortality after myocardial infarction.\textsuperscript{1,2} It is caused by left ventricle (LV) remodeling and subsequent papillary muscle (PM) displacement, with secondary mitral leaflet tethering. It can be seen classically in global LV dilatation and dysfunction or with more local remodeling involving the posterior PM and inferoposterior basal to mid LV wall.\textsuperscript{3} We report a case in which mitral leaflet tethering and severe MR occurred without either of these typical scenarios.

An 82-year-old woman presented to the emergency department for recent-onset progressive exertional dyspnea, orthopnea, and lower extremity edema. She had known hypertension with LV hypertrophy, normal systolic function, mitral annular calcification, and mild mitral regurgitation by echocardiogram 6 months previously. Medical history was notable for hyperlipidemia, transient ischemic attack, and family history of coronary artery disease.

Initial evaluation revealed overt heart failure with elevated NT-proBNP (>$9000$ pg/mL). Chest X-ray showed bilateral pleural effusions and pulmonary vascular redistribution (Figure 1). Cardiac troponins were negative, but ECG showed new T-wave inversions suggestive of anteroseptal ischemia (Figure 2). Echocardiogram revealed new regional wall motion abnormalities with inferopapillary dyskinesia and anteropapillary akinesis, but preserved motion of other segments, so that LV ejection fraction was $56\%$. There was incomplete closure of the mitral valve with apical tenting and severe MR by color Doppler (Figure 3A). Tall E wave on mitral inflow and blunted systolic pulmonary vein wave were consistent with severe MR, and the right ventricular systolic pressure was estimated at $73$ mm Hg (Figure 4). Importantly, the inferopapillary wall underlying the PM and the PM itself could be seen to thicken normally in apical and short-axis views (Figures 5, 6A, and 6B; Movies 1 and 2 in the online-only Data Supplement); in contrast, the inferior apex distal to the PM insertion was dyskinetic (Figure 5).

Stress adenosine SPECT showed a severe reversible apical defect. Cardiac catheterization showed a $90\%$ mid-left anterior descending artery (LAD) lesion. The patient underwent successful percutaneous coronary angioplasty with drug-eluting stenting of the mid-LAD, followed by rapid resolution of heart failure. Follow-up echocardiogram after 1 month showed only mild MR with vigorous LV (LV ejection fraction $80\%$) and improved pulmonary hypertension with markedly decreased RV systolic pressure to $39$ mm Hg (Figures 3 and 4). E wave was decreased and pulmonary vein systolic flow restored. Apical wall motion abnormalities had resolved along with mitral valve tethering (Figure 6C and 6D).

This patient is noteworthy for the absence of the 2 classical scenarios for ischemic MR. The LV was not dilated, and overall systolic function was preserved. The inferopapillary LV wall at the base and midventricle, along with the posterior PM, contracted normally in systole. On the other hand, there was dyskinesia of the inferopapillary segment secondary to severe stenosis of the LAD feeding this territory. Although ischemic MR was previously reported in patients with anterior and apical infarction,\textsuperscript{2} the underlying mechanisms have only been recently explored.\textsuperscript{4}

Echocardiographic observations are consistent with a severe mechanism in which tethering forces from apical bulging cause systolic restriction of the adjacent papillary muscle,
preventing adequate mitral valve closure and inducing MR. In this patient, LAD revascularization with subsequent resolution of the apical bulging caused dramatic improvement of MR severity, proving its ischemic origin.

Understanding the exact mechanism underlying MR is of utmost importance when choosing the appropriate therapy in each patient. Of note, radionuclide testing was consistent with viability in the affected region. Surgical revascularization with mitral valve replacement could have been considered, but careful analysis of the imaging data correctly identified the underlying mechanism and suggested that percutaneous LAD revascularization alone was needed to correct the MR.
