ACCF/AHA Practice Guideline
2013 ACCF/AHA Guideline for the
Management of Heart Failure
A Report of the American College of Cardiology Foundation/American
Heart Association Task Force on Practice Guidelines
Developed in Collaboration With the American College of Chest Physicians, Heart Rhythm Society and
International Society for Heart and Lung Transplantation
Endorsed by the American Association of Cardiovascular and Pulmonary Rehabilitation

Downloaded from http://circ.ahajournals.org/ by guest on June 6, 2017

Preamble
The medical profession should play a central role in evaluating the evidence related to drugs, devices, and procedures for the detection, management, and prevention of disease. When properly applied, expert analysis of available data on the benefits and risks of these therapies and procedures can improve the quality of care, optimize patient outcomes, and favorably affect costs by focusing resources on the most effective strategies. An organized and directed approach to a thorough review of evidence has resulted in the production of clinical practice guidelines that assist clinicians in selecting the best management strategy for an individual patient. Moreover, clinical practice guidelines can provide a foundation for other applications, such as performance measures, appropriate use criteria, and both quality improvement and clinical decision support tools.

The American College of Cardiology Foundation (ACCF) and the American Heart Association (AHA) have jointly produced guidelines in the area of cardiovascular disease since 1980. The ACCF/AHA Task Force on Practice Guidelines (Task Force), charged with developing, updating, and revising practice guidelines for cardiovascular diseases and procedures, directs and oversees this effort. Writing committees are charged with regularly reviewing and evaluating all available
In analyzing the data and developing recommendations and supporting text, the writing committee uses evidence-based methodologies developed by the Task Force. The Class of Recommendation (COR) is an estimate of the size of the treatment effect considering risks versus benefits in addition to evidence and/or agreement that a given treatment or procedure is or is not useful/effective or in some situations may cause harm. The Level of Evidence (LOE) is an estimate of the certainty or precision of the treatment effect. The writing committee reviews and ranks evidence supporting each recommendation with the weight of evidence ranked as LOE A, B, or C according to specific definitions that are included in Table 1. Studies are identified as observational, retrospective, prospective, or randomized where appropriate. For certain conditions for which inadequate data are available, recommendations
are based on expert consensus and clinical experience and are ranked as LOE C. When recommendations at LOE C are supported by historical clinical data, appropriate references (including clinical reviews) are cited if available. For issues for which sparse data are available, a survey of current practice among the clinicians on the writing committee is the basis for LOE C recommendations and no references are cited. The schema for COR and LOE are summarized in Table 1, which also provides suggested phrases for writing recommendations within each COR. A new addition to this methodology is separation of the Class III recommendations to delineate whether the recommendation is determined to be of “no benefit” or is associated with “harm” to the patient. In addition, in view of the increasing number of comparative effectiveness studies, comparative verbs and suggested phrases for writing recommendations for the comparative effectiveness of one treatment or strategy versus another have been added for COR I and IIa, LOE A or B only.

In view of the advances in medical therapy across the spectrum of cardiovascular diseases, the Task Force has designated the term guideline-directed medical therapy (GDMT) to represent optimal medical therapy as defined by ACCF/AHA guideline–recommended therapies (primarily Class I). This new term, GDMT, will be used herein and throughout all future guidelines.

Because the ACCF/AHA practice guidelines address patient populations (and clinicians) residing in North America, drugs that are not currently available in North America are discussed in the text without a specific COR. For studies performed in large numbers of subjects outside North America, each writing committee reviews the potential influence of different practice patterns and patient populations on the treatment effect and relevance to the ACCF/AHA target population to determine whether the findings should inform a specific recommendation.

The ACCF/AHA practice guidelines are intended to assist clinicians in clinical decision making by describing a range of generally acceptable approaches to the diagnosis, management, and prevention of specific diseases or conditions. The guidelines attempt to define practices that meet the needs of most patients in most circumstances. The ultimate judgment regarding care of a particular patient must be made by the clinician and patient in light of all the circumstances presented by that patient. As a result, situations may arise for which deviations from these guidelines may be appropriate. Clinical decision making should involve consideration of the quality and availability of expertise in the area where care is provided. When these guidelines are used as the basis for regulatory or payer decisions, the goal should be improvement in quality of care. The Task Force recognizes that situations arise in which additional data are needed to inform patient care more effectively; these areas will be identified within each respective guideline when appropriate.

Prescribed courses of treatment in accordance with these recommendations are effective only if followed. Because lack of patient understanding and adherence may adversely affect outcomes, clinicians should make every effort to engage the patient’s active participation in prescribed medical regimens and lifestyles. In addition, patients should be informed of the risks, benefits, and alternatives to a particular treatment and be involved in shared decision making whenever feasible, particularly for COR IIa and IIb, for which the benefit-to-risk ratio may be lower.

The Task Force makes every effort to avoid actual, potential, or perceived conflicts of interest that may arise as a result of industry relationships or personal interests among the members of the writing committee. All writing committee members and peer reviewers of the guideline are required to disclose all current healthcare-related relationships, including those existing 12 months before initiation of the writing effort. In December 2009, the ACCF and AHA implemented a new policy for relationship with industry and other entities (RWI) that requires the writing committee chair plus a minimum of 50% of the writing committee to have no relevant RWI (Appendix 1 includes the ACCF/AHA definition of relevance). These statements are reviewed by the Task Force and all members during each conference call and/or meeting of the writing committee and are updated as changes occur. All guideline recommendations require a confidential vote by the writing committee and must be approved by a consensus of the voting members. Members are not permitted to draft or vote on any text or recommendations pertaining to their RWI. Members who recused themselves from voting are indicated in the list of writing committee members, and specific section recusals are noted in Appendix 1. Authors’ and peer reviewers’ RWI pertinent to this guideline are disclosed in Appendixes 1 and 2, respectively. Additionally, to ensure complete transparency, writing committee members’ comprehensive disclosure information—including RWI not pertinent to this document—is available as an online supplement. Comprehensive disclosure information for the Task Force is also available online at http://www.cardiosource.org/en/ACC/About-ACC/Who-We-Are/Leadership/Guidelines-and-Documents-Task-Forces.aspx. The work of writing committees is supported exclusively by the ACCF and AHA without commercial support. Writing committee members volunteered their time for this activity.

In an effort to maintain relevance at the point of care for practicing clinicians, the Task Force continues to oversee an ongoing process improvement initiative. As a result, in response to pilot projects, several changes to these guidelines will be apparent, including limited narrative text, a focus on summary and evidence tables (with references linked to abstracts in PubMed), and more liberal use of summary recommendation tables (with references that support LOE) to serve as a quick reference.

In April 2011, the Institute of Medicine released 2 reports: Clinical Practice Guidelines We Can Trust and Finding What Works in Health Care: Standards for Systematic Reviews. It is noteworthy that the ACCF/AHA practice guidelines are cited as being compliant with many of the proposed standards. A thorough review of these reports and of our current methodology is under way, with further enhancements anticipated.

The recommendations in this guideline are considered current until they are superseded by a focused update or the full-text guideline is revised. Guidelines are official policy of both the ACCF and AHA.

Jeffrey L. Anderson, MD, FACC, FAHA
Chair, ACCF/AHA Task Force on Practice Guidelines
1. Introduction

1.1. Methodology and Evidence Review

The recommendations listed in this document are, whenever possible, evidence based. An extensive evidence review was conducted through October 2011 and includes selected other references through April 2013. Searches were extended to studies, reviews, and other evidence conducted in human subjects and that were published in English from PubMed, EMBASE, Cochrane, Agency for Healthcare Research and Quality Reports, and other selected databases relevant to this guideline. Key search words included but were not limited to the following: heart failure, cardiomyopathy, quality of life, mortality, hospitalizations, prevention, biomarkers, hypertension, dyslipidemia, imaging, cardiac catheterization, endomyocardial biopsy, angiotensin-converting enzyme inhibitors, angiotensin-receptor antagonists/blockers, beta blockers, cardiac, cardiac resynchronization therapy, defibrillator, device-based therapy, implantable cardioverter-defibrillator, device implantation, medical therapy, acute decompensated heart failure, preserved ejection fraction, terminal care and transplantation, quality measures, and performance measures. Additionally, the committee reviewed documents related to the subject matter previously published by the ACCF and AHA. References selected and published in this document are representative and not all-inclusive.

To provide clinicians with a representative evidence base, whenever deemed appropriate or when published, the absolute risk difference and number needed to treat or harm are provided in the guideline (within tables), along with confidence intervals and data related to the relative treatment effects such as odds ratio, relative risk, hazard ratio, and incidence rate ratio.

1.2. Organization of the Writing Committee

The committee was composed of physicians and a nurse with broad expertise in the evaluation, care, and management of patients with heart failure (HF). The authors included general cardiologists, HF and transplant specialists, electrophysiologists, general internists, and physicians with methodological expertise. The committee included representatives from the ACCF, AHA, American Academy of Family Physicians, American College of Chest Physicians, American College of Physicians, Heart Rhythm Society, and International Society for Heart and Lung Transplantation.

1.3. Document Review and Approval

This document was reviewed by 2 official reviewers each nominated by both the ACCF and the AHA, as well as 1 to 2 reviewers each from the American Academy of Family Physicians, American College of Chest Physicians, Heart Rhythm Society, and International Society for Heart and Lung Transplantation, as well as 32 individual content reviewers (including members of the ACCF Adult Congenital and Pediatric Cardiology Council, ACCF Cardiovascular Team Council, ACCF Council on Cardiovascular Care for Older Adults, ACCF Electrophysiology Committee, ACCF Heart Failure and Transplant Council, ACCF Imaging Council, ACCF Prevention Committee, ACCF Surgeons’ Scientific Council, and ACCF Task Force on Appropriate Use Criteria).

All information on reviewers’ RWI was distributed to the writing committee and is published in this document (Appendix 2). This document was approved for publication by the governing bodies of the ACCF and AHA and endorsed by the American Association of Cardiovascular and Pulmonary Rehabilitation, American College of Chest Physicians, Heart Rhythm Society, and International Society for Heart and Lung Transplantation.

1.4. Scope of This Guideline With Reference to Other Relevant Guidelines or Statements

This guideline covers multiple management issues for the adult patient with HF. Although there is an abundance of evidence addressing HF, for many important clinical considerations, this writing committee was unable to identify sufficient data to properly inform a recommendation. The writing committee actively worked to reduce the number of LOE “C” recommendations, especially for Class I–recommended therapies. Despite these limitations, it is apparent that much can be done for HF. Adherence to the clinical practice guidelines herein reproduced should lead to improved patient outcomes.

Although of increasing importance, HF in children and congenital heart lesions in adults are not specifically addressed in this guideline. The reader is referred to publically available resources to address questions in these areas. However, this guideline does address HF with preserved ejection fraction (EF) in more detail and similarly revisits hospitalized HF. Additional areas of renewed interest are in stage D HF, palliative care, transition of care, and quality of care for HF. Certain management strategies appropriate for the patient at risk for HF or already affected by HF are also reviewed in numerous relevant clinical practice guidelines and scientific statements published by the ACCF/AHA Task Force on Practice Guidelines, AHA, ACCF Task Force on Appropriate Use Criteria, European Society of Cardiology, Heart Failure Society of America, and the National Heart, Lung, and Blood Institute. The writing committee saw no need to reiterate the recommendations contained in those guidelines and chose to harmonize recommendations when appropriate and eliminate discrepancies. This is especially the case for device-based therapeutics, where complete alignment between the HF guideline and the device-based therapy guideline was deemed imperative.4 Some recommendations from earlier guidelines have been updated as warranted by new evidence or a better understanding of earlier evidence, whereas others that were no longer accurate or relevant or which were overlapping were modified; recommendations from previous guidelines that were similar or redundant were eliminated or consolidated when possible.

The present document recommends a combination of lifestyle modifications and medications that constitute GDMT. GDMT is specifically referenced in the recommendations for the treatment of HF (Section 7.3.2). Both for GDMT and other recommended drug treatment regimens, the reader is advised to confirm dosages with product insert material and to evaluate carefully for contraindications and drug-drug interactions. Table 2 is a list of documents deemed pertinent to this effort and is intended for use as a resource; it obviates the need to repeat already extant guideline recommendations. Additional other HF guideline statements are highlighted as well for the purpose of comparison and completeness.
2. Definition of HF

HF is a complex clinical syndrome that results from any structural or functional impairment of ventricular filling or ejection of blood. The cardinal manifestations of HF are dyspnea and fatigue, which may limit exercise tolerance, and fluid retention, which may lead to pulmonary and/or splanchnic congestion and/or peripheral edema. Some patients have exercise intolerance but little evidence of fluid retention, whereas others complain primarily of edema, dyspnea, or fatigue. Because some patients present without signs or symptoms of volume overload, the term “heart failure” is preferred over “congestive heart failure.” There is no single diagnostic test for HF because it is largely a clinical diagnosis based on a careful history and physical examination.

The clinical syndrome of HF may result from disorders of the pericardium, myocardium, endocardium, heart valves, or great vessels or from certain metabolic abnormalities, but most patients with HF have symptoms due to impaired left ventricular (LV) myocardial function. It should be emphasized

that HF is not synonymous with either cardiomyopathy or LV dysfunction; these latter terms describe possible structural or functional reasons for the development of HF. HF may be associated with a wide spectrum of LV functional abnormalities, which may range from patients with normal LV size and preserved EF to those with severe dilatation and/or markedly reduced EF. In most patients, abnormalities of systolic and diastolic dysfunction coexist, irrespective of EF. EF is considered important in classification of patients with HF because of differing patient demographics, comorbid conditions, prognosis, and response to therapies\(^3\) and because most clinical trials selected patients based on EF. EF values are dependent on the imaging technique used, method of analysis, and operator. Because other techniques may indicate abnormalities in systolic function among patients with a preserved EF, it is preferable to use the terms preserved or reduced EF over preserved or reduced systolic function. For the remainder of this guideline, we will consistently refer to HF with preserved EF and HF with reduced EF as HF\(_p\)EF and HF\(_r\)EF, respectively (Table 3).

### 2.1. HF With Reduced EF (HF\(_r\)EF)

In approximately half of patients with HF\(_r\)EF, variable degrees of LV enlargement may accompany HF\(_r\)EF.\(^6\),\(^7\) The definition of LV EF has varied, with guidelines of left ventricular ejection fraction (LVEF) \(\leq 35\%\), \(< 40\%\), and \(\leq 40\%\).\(^8\),\(^9\),\(^10\) Randomized controlled trials (RCTs) in patients with HF have mainly enrolled patients with HF\(_r\)EF with an EF \(\leq 35\%\) or \(\leq 40\%\), and it is only in these patients that efficacious therapies have been demonstrated to date. For the present guideline, HF\(_r\)EF is defined as the clinical diagnosis of HF and EF \(\leq 40\%\). Those with LV systolic dysfunction commonly have elements of diastolic dysfunction as well.\(^9\) Although coronary artery disease (CAD) with antecedent myocardial infarction (MI) is a major cause of HF\(_r\)EF, many other risk factors (Section 4.6) may lead to LV enlargement and HF\(_r\)EF.

### 2.2. HF With Preserved EF (HF\(_p\)EF)

In patients with clinical HF, studies estimate that the prevalence of HF\(_p\)EF is approximately 50% (range \(40\%\) to \(71\%\)).\(^4\) These estimates vary largely because of the differing EF cutoff criteria and challenges in diagnostic criteria for HF\(_p\)EF. HF\(_p\)EF has been variably classified as EF \(> 40\%, > 45\%, > 50\%, \) and \(\geq 55\%\). Because some of these patients do not have entirely normal EF but also do not have major reduction in systolic function, the term preserved EF has been used. Patients with an EF in the range of \(40\%\) to \(50\%\) represent an intermediate group. These patients are often treated for underlying risk factors and comorbidities and with GDMT similar to that used in patients with HF\(_r\)EF. Several criteria have been proposed to define the syndrome of HF\(_p\)EF. These include a) clinical signs or symptoms of HF; b) evidence of preserved or normal LVEF; and c) evidence of abnormal LV diastolic dysfunction that can be determined by Doppler echocardiography or cardiac catheterization.\(^4\) The diagnosis of HF\(_p\)EF is more challenging than the diagnosis of HF\(_r\)EF because it is largely one of excluding other potential noncardiac causes of symptoms suggestive of HF. Studies have suggested that the incidence of HF\(_p\)EF is increasing and that a greater portion of patients hospitalized with HF have HF\(_p\)EF.\(^2\) In the general population, patients with HF\(_p\)EF are usually older women with a history of hypertension. Obesity, CAD, diabetes mellitus, atrial fibrillation (AF), and hyperlipidemia are also highly prevalent in HF\(_p\)EF in population-based studies and registries.\(^9\),\(^10\),\(^13\) Despite these associated cardiovascular risk factors, hypertension remains the most important cause of HF\(_p\)EF; with a prevalence of \(60\%\) to \(89\%\) from large controlled trials, epidemiological studies, and HF registries.\(^4\) It has been recognized that a subset of patients with HF\(_p\)EF previously had HF\(_r\)EF.\(^4\) These patients with improvement or recovery in EF may be clinically distinct from those with persistently preserved or reduced EF. Further research is needed to better characterize these patients.

See Online Data Supplement 1 for additional data on HF\(_p\)EF.

### 3. HF Classifications

Both the ACCF/AHA stages of HF\(^2\),\(^8\),\(^16\) and the New York Heart Association (NYHA) functional classification\(^11\),\(^18\) provide useful and complementary information about the presence and severity of HF. The ACCF/AHA stages of HF emphasize the development and progression of disease and can be used to describe individuals and populations, whereas the NYHA classes focus on exercise capacity and the symptomatic status of the disease (Table 4).

Further research is needed to better characterize these patients.</td>
</tr>
</tbody>
</table>

EF indicates ejection fraction; HF, heart failure; HF\(_p\)EF, heart failure with preserved ejection fraction; and HF\(_r\)EF, heart failure with reduced ejection fraction.
The ACCF/AHA stages of HF recognize that both risk factors and abnormalities of cardiac structure are associated with HF. The stages are progressive and inviolate; once a patient moves to a higher stage, regression to an earlier stage of HF is not observed. Progression in HF stages is associated with reduced 5-year survival and increased plasma natriuretic peptide concentrations. Therapeutic interventions in each stage aimed at modifying risk factors (stage A), treating structural heart disease (stage B), and reducing morbidity and mortality (stages C and D) (covered in detail in Section 7) are reviewed in this document. The NYHA functional classification gauges the severity of symptoms in those with structural heart disease, primarily stages C and D. It is a subjective assessment by a clinician and can change frequently over short periods of time. Although reproducibility and validity may be problematic, the NYHA functional classification is an independent predictor of mortality. It is widely used in clinical practice and research and for determining the eligibility of patients for certain healthcare services.

See Online Data Supplement 2 for additional data on ACCF/AHA stages of HF and NYHA functional classifications.

### 4. Epidemiology

The lifetime risk of developing HF is 20% for Americans ≥40 years of age. In the United States, HF incidence has largely remained stable over the past several decades, with >650,000 new HF cases diagnosed annually. HF incidence increases with age, rising from approximately 20 per 1000 individuals 65 to 69 years of age to >80 per 1000 individuals among those ≥85 years of age. Approximately 5.1 million persons in the United States have clinically manifest HF, and the prevalence remained stable over the past several decades, with >650,000 HF cases diagnosed annually. In the United States, HF incidence has largely increased from 90 to 121 per 1000 beneficiaries >65 years of age by 2050. Because HF prevalence is highest in this group, the number of Americans with HF is expected to significantly worsen in the future. Disparities in the epidemiology of HF have been identified. Blacks have the highest risk for HF. In the ARIC (Atherosclerosis Risk in Communities) study, incidence rate per 1000 person-years was lowest among white women and highest among black men, with blacks having a greater 5-year mortality rate than whites. HF in non-Hispanic black males and females has a prevalence of 4.5% and 3.8%, respectively, versus 2.7% and 1.8% in non-Hispanic white males and females, respectively.

#### 4.1. Mortality

Although survival has improved, the absolute mortality rates for HF remain approximately 50% within 5 years of diagnosis. In the ARIC study, the 30-day, 1-year, and 5-year case fatality rates after hospitalization for HF were 10.4%, 22%, and 42.3%, respectively. In another population cohort study with 5-year mortality data, survival for stage A, B, C, and D HF was 97%, 96%, 75%, and 20%, respectively. Thirty-day postdischarge mortality rates decreased from 12.6% to 10.8% from 1993 to 2005; however, this was due to lower in-hospital death rates. Postdischarge mortality actually increased from 4.3% to 6.4% during the same time frame. These observed temporal trends in HF survival are primarily restricted to patients with reduced EF and are not seen in those with preserved EF.

See Online Data Supplement 3 for additional data on mortality.

#### 4.2. Hospitalizations

HF is the primary diagnosis in >1 million hospitalizations annually. Patients hospitalized for HF are at high risk for all-cause rehospitalization, with a 1-month readmission rate of 25%. In 2013, physician office visits for HF cost $1.8 billion. The total cost of HF care in the United States exceeds $30 billion annually, with over half of these costs spent on hospitalizations.

#### 4.3. Asymptomatic LV Dysfunction

The prevalence of asymptomatic LV systolic or diastolic dysfunction ranges from 6% to 21% and increases with age. In the Left Ventricular Dysfunction Prevention study, participants with untreated asymptomatic LV dysfunction had a 10% risk for developing HF symptoms and an 8% risk of death or HF hospitalization annually. In a community-based population, asymptomatic mild LV diastolic dysfunction was seen in 21% and moderate or severe diastolic dysfunction in 7%, and both were associated with an increased risk of symptomatic HF and mortality.
4.4. Health-Related Quality of Life and Functional Status

HF significantly decreases health-related quality of life (HRQOL), especially in the areas of physical functioning and vitality.56,65 Lack of improvement in HRQOL after discharge from the hospital is a powerful predictor of rehospitalization and mortality.68,69 Women with HF have consistently been found to have poorer HRQOL than men.67,70 Ethnic differences also have been found, with Mexican Hispanics reporting better HRQOL than other ethnic groups in the United States.71 Other determinants of poor HRQOL include depression, younger age, higher body mass index (BMI), greater symptom burden, lower systolic blood pressure, sleep apnea, low perceived control, and uncertainty about prognosis.70,72–76 Memory problems may also contribute to poor HRQOL.76

Pharmacological therapy is not a consistent determinant of HRQOL; therapies such as angiotensin-converting enzyme (ACE) inhibitors and angiotensin-receptor blockers (ARBs) improve HRQOL only modestly or delay the progressive worsening of HRQOL in HF.77 At present, the only therapies shown to improve HRQOL are cardiac resynchronization therapy (CRT)78 and certain disease management and educational approaches.79–82 Self-care and exercise may improve HRQOL, but the results of studies evaluating these interventions are mixed.83–86 Throughout this guideline we refer to meaningful survival as a state in which HRQOL is satisfactory to the patient.

See Online Data Supplement 4 for additional data on HRQOL and functional capacity.

4.5. Economic Burden of HF

In 1 in 9 deaths in the United States, HF is mentioned on the death certificate. The number of deaths with any mention of HF was as high in 2006 as it was in 1995.51 Approximately 7% of all cardiovascular deaths are due to HF.

As previously noted, in 2013, HF costs in the United States exceeded $30 billion.51 This total includes the cost of healthcare services, medications, and lost productivity. The mean cost of HF-related hospitalizations was $23,077 per patient and was higher when HF was a secondary rather than the primary diagnosis. Among patients with HF in 1 large population study, hospitalizations were common after HF diagnosis, with 83% of patients hospitalized at least once and 43% hospitalized at least 4 times. More than half of the hospitalizations were related to noncardiovascular causes.87–89

4.6. Important Risk Factors for HF (Hypertension, Diabetes Mellitus, Metabolic Syndrome, and Atherosclerotic Disease)

Many conditions or comorbidities are associated with an increased propensity for structural heart disease. The expedient identification and treatment of these comorbid conditions may forestall the onset of HF.14,27,90 A list of the important documents that codify treatment for these concomitant conditions appears in Table 2.

Hypertension

Hypertension may be the single most important modifiable risk factor for HF in the United States. Hypertensive men and women have a substantially greater risk for developing HF than normotensive men and women.91 Elevated levels of diastolic and especially systolic blood pressure are major risk factors for the development of HF.91,92 The incidence of HF is greater with higher levels of blood pressure, older age, and longer duration of hypertension. Long-term treatment of both systolic and diastolic hypertension reduces the risk of HF by approximately 50%,93–96 With nearly a quarter of the American population afflicted by hypertension and the lifetime risk of developing hypertension at >75% in the United States,97 strategies to control hypertension are a vital part of any public health effort to prevent HF.

Diabetes Mellitus

Obesity and insulin resistance are important risk factors for the development of HF.98,99 The presence of clinical diabetes mellitus markedly increases the likelihood of developing HF in patients without structural heart disease100 and adversely affects the outcomes of patients with established HF.101,102

Metabolic Syndrome

The metabolic syndrome includes any 3 of the following: abdominal adiposity, hypertriglyceridemia, low high-density lipoprotein, hypertension, and fasting hyperglycemia. The prevalence of metabolic syndrome in the United States exceeds 20% of persons ≥20 years of age and 40% of those >40 years of age.103 The appropriate treatment of hypertension, diabetes mellitus, and dyslipidemia104 can significantly reduce the development of HF.

Atherosclerotic Disease

Patients with known atherosclerotic disease (eg, of the coronary, cerebral, or peripheral blood vessels) are likely to develop HF, and clinicians should seek to control vascular risk factors in such patients according to guidelines.13

5. Cardiac Structural Abnormalities and Other Causes of HF

5.1. Dilated Cardiomyopathies

5.1.1. Definition and Classification of Dilated Cardiomyopathies

Dilated cardiomyopathy (DCM) refers to a large group of heterogeneous myocardial disorders that are characterized by ventricular dilation and depressed myocardial contractility in the absence of abnormal loading conditions such as hypertension or valvular disease. In clinical practice and multicenter HF trials, the etiology of HF has often been categorized into ischemic or nonischemic cardiomyopathy, with the term DCM used interchangeably with nonischemic cardiomyopathy. This approach fails to recognize that “nonischemic cardiomyopathy” may include cardiomyopathies due to volume or pressure overload, such as hypertension or valvular heart disease, which are not conventionally accepted as DCM.105 With the identification of genetic defects in several forms of cardiomyopathies, a new classification scheme based on genomics was proposed in 2006.106 We recognize that classification of cardiomyopathies is challenging, mixing anatomic designations (ie, hypertrophic and dilated) with functional designations (ie, restrictive), and is unlikely to satisfy all users. The aim of the
present guideline is to target appropriate diagnostic and treatment strategies for preventing the development and progression of HF in patients with cardiomyopathies; we do not wish to redefine new classification strategies for cardiomyopathies.

5.1.2. Epidemiology and Natural History of DCM
The age-adjusted prevalence of DCM in the United States averages 36 cases per 100,000 population, and DCM accounts for 10,000 deaths annually.106 In most multicenter RCTs and registries in HF, approximately 30% to 40% of enrolled patients have DCM.107–109 Compared with whites, African Americans have almost a 3-fold increased risk for developing DCM, irrespective of comorbidities or socioeconomic factors.108–110 Sex-related differences in the incidence and prognosis of DCM are conflicting and may be confounded by differing etiologies.108,109,111 The prognosis in patients with symptomatic HF and DCM is relatively poor, with 25% mortality at 1 year and 50% mortality at 5 years.112 Approximately 25% of patients with DCM with recent onset of HF symptoms will improve within a short time even in the absence of optimal GDMT,113 but patients with symptoms lasting >3 months who present with severe chronic decompensation generally have less chance of recovery.114 Patients with idiopathic DCM have a lower total mortality rate than patients with other types of DCM.114 However, GDMT is beneficial in all forms of DCM.78,109,115–117

5.2. Familial Cardiomyopathies
Increasingly, it is recognized that many (20% to 35%) patients with an idiopathic DCM have a familial cardiomyopathy (defined as 2 closely related family members who meet the criteria for idiopathic DCM).118,119 Consideration of familial cardiomyopathies includes the increasingly important discovery of noncompaction cardiomyopathies. Advances in technology permitting high-throughput sequencing and genotyping at reduced costs have brought genetic screening to the clinical arena. For further information on this topic, the reader is referred to published guidelines, position statements, and expert consensus statements118,120–123 (Table 5).

5.3. Endocrine and Metabolic Causes of Cardiomyopathy
5.3.1. Obesity
Obesity cardiomyopathy is defined as cardiomyopathy due entirely or predominantly to obesity (Section 7.3.1.5). Although the precise mechanisms causing obesity-related HF are not known, excessive adipose accumulation results in an increase in circulating blood volume. A subsequent, persistent increase in cardiac output, cardiac work, and systemic blood pressure along with lipotoxicity-induced cardiac myocyte injury and myocardial lipid accumulation have been implicated as potential mechanisms.125,126 A study with participants from the Framingham Heart Study reported that after adjustment for established risk factors, obesity was associated with significant future risk of development of HF.99 There are no large-scale studies of the safety or efficacy of weight loss with diet, exercise, or bariatric surgery in obese patients with HF.

5.3.2. Diabetic Cardiomyopathy
Diabetes mellitus is now well recognized as a risk factor for the development of HF independent of age, hypertension, obesity, hypercholesterolemia, or CAD. The association between mortality and hemoglobin A1c (HbA1c) in patients with diabetes mellitus and HF appears U-shaped, with the lowest risk of death in those patients with modest glucose control (7.1%<HbA1c≤7.8%) and with increased risk with extremely high or low HbA1c levels.127 The optimal treatment strategy in patients with diabetes mellitus and HF is controversial; some studies have suggested potential harm with several glucose-lowering medications.127,128 The safety and efficacy of diabetes mellitus therapies in HF, including metformin, sulfonlureas, insulin, and glucagon-like peptide analogues, await further data from prospective clinical trials.129–131 Treatment with thiazolidinediones (eg, rosiglitazone) is associated with fluid retention in patients with HF129,132 and should be avoided in patients with NYHA class II through IV HF.

5.3.3. Thyroid Disease
Hyperthyroidism has been implicated in causing DCM but most commonly occurs with persistent sinus tachycardia or atrial fibrillation and may be related to tachycardia.133 Abnormalities in cardiac systolic and diastolic performance have been reported in hypothyroidism. However, the classic findings of myxedema do not usually indicate cardiomyopathy. The low cardiac output results from bradycardia, decreased ventricular filling, reduced cardiac contractility, and diminished myocardial work.133,134

5.3.4. Acromegaly and Growth Hormone Deficiency
Impaired cardiovascular function has been associated with reduced life expectancy in patients with growth hormone deficiency and excess. Experimental and clinical studies implicate growth hormone and insulin-like growth factor I in cardiac development.135 Cardiomyopathy associated with acromegaly is characterized by myocardial hypertrophy with intersitial fibrosis, lympho-mononuclear infiltration, myocyte necrosis, and biventricular concentric hypertrophy.135

DCM indicates dilated cardiomyopathy; and LV, left ventricular.
5.4. Toxic Cardiomyopathy

5.4.1. Alcoholic Cardiomyopathy
Chronic alcoholism is one of the most important causes of DCM. The clinical diagnosis is suspected when biventricular dysfunction and dilatation are persistently observed in a heavy drinker in the absence of other known causes for myocardial disease. Alcoholic cardiomyopathy most commonly occurs in men 30 to 55 years of age who have been heavy consumers of alcohol for >10 years. Women represent approximately 14% of the alcoholic cardiomyopathy cases but may be more vulnerable with less lifetime alcohol consumption. The risk of asymptomatic alcoholic cardiomyopathy is increased in those consuming >90 g of alcohol per day (approximately 7 to 8 standard drinks per day) for >5 years. Interestingly, in the general population, mild to moderate alcohol consumption has been reported to be protective against development of HF. These paradoxical findings suggest that duration of exposure and individual genetic susceptibility play an important role in pathogenesis. Recovery of LV function after cessation of drinking has been reported. Even if LV dysfunction persists, the symptoms and signs of HF improve after abstinence.

5.4.2. Cocaine Cardiomyopathy
Long-term abuse of cocaine may result in DCM even without CAD, vasculitis, or MI. Depressed LV function has been reported in 4% to 18% of asymptomatic cocaine abusers. The safety and efficacy of beta blockers for chronic HF due to cocaine use are unknown.

5.4.3. Cardiotoxicity Related to Cancer Therapies
Several cytotoxic antineoplastic drugs, especially the anthracyclines, are cardiotoxic and can lead to long-term cardiac morbidity. Iron-chelating agents that prevent generation of oxygen free radicals, such as dexrazoxane, are cardioprotective, and reduce the occurrence and severity of anthracycline-induced cardiotoxicity and development of HF.

Other antineoplastic chemotherapies with cardiotoxicity are the monoclonal antibody trastuzumab (Herceptin), high-dose cyclophosphamide, taxoids, mitomycin-C, 5-fluorouracil, and the interferons. In contrast to anthracycline-induced cardiac toxicity, trastuzumab-related cardiac dysfunction does not appear to increase with cumulative dose, nor is it associated with ultrastructural changes in the myocardium. However, concomitant anthracycline therapy significantly increases the risk for cardiotoxicity during trastuzumab treatment. The cardiac dysfunction associated with trastuzumab is most often reversible on discontinuation of treatment and initiation of standard medical therapy for HF. The true incidence and reversibility of chemotherapy-related cardiotoxicity are not well documented, and meaningful interventions to prevent injury have not yet been elucidated.

5.4.4. Other Myocardial Toxins and Nutritional Causes of Cardiomyopathy
In addition to the classic toxins described above, a number of other toxic agents may lead to LV dysfunction and HF, including ephedra, cobalt, anabolic steroids, chloroquine, clozapine,amphetamine, methylphenidate, and catecholamines. Ephedra, which has been used for athletic performance enhancement and weight loss, was ultimately banned by the US Food and Drug Administration for its high rate of adverse cardiovascular outcomes, including LV systolic dysfunction, development of HF, and sudden cardiac death (SCD). Primary and secondary nutritional deficiencies may lead to cardiomyopathy. Chronic alcoholism, anorexia nervosa, AIDS, and pregnancy can account for other rare causes of thiamine deficiency–related cardiomyopathy in the western world. Deficiency in L-carnitine, a necessary cofactor for fatty acid oxidation, may be associated with a syndrome of progressive skeletal myopathy and cardiomyopathy.

5.5. Tachycardia-Induced Cardiomyopathy
Tachycardia-induced cardiomyopathy is a reversible cause of HF characterized by LV myocardial dysfunction caused by increased ventricular rate. The degree of dysfunction correlates with the duration and rate of the tachyarrhythmia. Virtually any supraventricular tachycardia with a rapid ventricular response may induce cardiomyopathy. Ventricular arrhythmias, including frequent premature ventricular complexes, may also induce cardiomyopathy. Maintenance of sinus rhythm or control of ventricular rate is critical to treating patients with tachycardia-induced cardiomyopathy. Reversibility of the cardiomyopathy with treatment of the arrhythmia is the rule, although this may not be complete in all cases. The underlying mechanisms for this are not well understood.

Ventricular pacing at high rates may cause cardiomyopathy. Additionally, right ventricular pacing alone may exacerbate HF symptoms, increase hospitalization for HF, and increase mortality. Use of CRT in patients with a conduction delay due to pacing may result in improved LV function and functional capacity.

5.6. Myocarditis and Cardiomyopathies Due to Inflammation

5.6.1. Myocarditis
Inflammation of the heart may cause HF in about 10% of cases of initially unexplained cardiomyopathy. A variety of infectious organisms, as well as toxins and medications, most often postviral in origin, may cause myocarditis. In addition, myocarditis is also seen as part of other systemic diseases such as systemic lupus erythematosus and other myocardial muscle diseases such as HIV cardiomyopathy and possibly peripartum cardiomyopathy. Presentation may be acute, with a distinct onset, severe hemodynamic compromise, and severe LV dysfunction as seen in acute fulminant myocarditis, or it may be subacute, with an indistinct onset and better-tolerated LV dysfunction. Prognosis varies, with spontaneous complete resolution (paradoxically most often seen with acute fulminant myocarditis) to the development of DCM despite immunosuppressive therapy. The role of immunosuppressive therapy is controversial. Targeting such therapy to specific individuals based on the presence or absence of viral genome in myocardial biopsy samples may improve response to immunosuppressive therapy.

Giant cell myocarditis is a rare form of myocardial inflammation characterized by fulminant HF, often associated with refractory ventricular arrhythmias and a poor prognosis.
Histologic findings include diffuse myocardial necrosis with numerous multinucleated giant cells without granuloma formation. Consideration for advanced HF therapies, including immunosuppression, mechanical circulatory support (MCS), and transplantation, is warranted.

5.6.2. Acquired Immunodeficiency Syndrome
The extent of immunodeficiency influences the incidence of HIV-associated DCM. In long-term echocardiographic follow-up, 8% of initially asymptomatic HIV-positive patients were diagnosed with DCM during the 5-year follow-up. Whether early treatment with ACE inhibitors and/or beta blockers will prevent or delay disease progression in these patients is unknown at this time.

5.6.3. Chagas Disease
Although Chagas disease is a relatively uncommon cause of DCM in North America, it remains an important cause of death in Central and South America. Symptomatic chronic Chagas disease develops in an estimated 10% to 30% of infected persons, years or even decades after the Trypanosoma cruzi infection. Cardiac changes may include biventricular enlargement, thinning or thickening of ventricular walls, apical aneurysms, and mural thrombi. The conduction system is often affected, typically resulting in right bundle-branch block, left anterior fascicular block, or complete atrioventricular block.

5.7. Inflammation-Induced Cardiomyopathy: Noninfectious Causes
5.7.1. Hypersensitivity Myocarditis
Hypersensitivity to a variety of agents may result in allergic reactions that involve the myocardium, characterized by peripheral eosinophilia and a perivascular infiltration of the myocardium by eosinophils, lymphocytes, and histiocytes. A variety of drugs, most commonly the sulfonamides, penicillins, methyldopa, and other agents such as amphotericin B, streptomycin, phenytoin, isoniazid, tetanus toxoid, hydrochlorothiazide, dobutamine, and chlorthallidone, have been reported to cause allergic hypersensitivity myocarditis. Most patients are not clinically ill but may die suddenly, presumably secondary to an arrhythmia.

5.7.2. Rheumatological/Connective Tissue Disorders
Along with a number of cardiac abnormalities (eg, pericarditis, pericardial effusion, conduction system abnormalities, including complete atrioventricular heart block), DCM can be a rare manifestation of systemic lupus erythematosus and usually correlates with disease activity. Studies suggest that echocardiographic evidence of abnormal LV filling may reflect the presence of myocardial fibrosis and could be a marker of subclinical myocardial involvement in systemic lupus erythematosus patients. Scleroderma is a rare cause of DCM. One echocardiographic study showed that despite normal LV dimensions or fractional shortening, subclinical systolic impairment was present in the majority of patients with scleroderma. Cardiac involvement in rheumatoid arthritis generally is in the form of myocarditis and/or pericarditis, and development of DCM is rare. Myocardial involvement in rheumatoid arthritis is thought to be secondary to microvascularitis and subsequent microcirculatory disturbances. Myocardial disease in rheumatoid arthritis can occur in the absence of clinical symptoms or abnormalities of the electrocardiogram (ECG).

5.8. Peripartum Cardiomyopathy
Peripartum cardiomyopathy is a disease of unknown cause in which LV dysfunction occurs during the last trimester of pregnancy or the early puerperium. It is reported in 1:1300 to 1:4000 live births. Risk factors for peripartum cardiomyopathy include advanced maternal age, multiparity, African descent, and long-term tocology. Although its etiology remains unknown, most theories have focused on hemodynamic and immunologic causes. The prognosis of peripartum cardiomyopathy is related to the recovery of ventricular function. Significant improvement in myocardial function is seen in 30% to 50% of patients in the first 6 months after presentation. However, for those patients who do not recover to normal or near-normal function, the prognosis is similar to other forms of DCM. Cardiomegaly that persists for >4 to 6 months after diagnosis indicates a poor prognosis, with a 50% mortality rate at 6 years. Subsequent pregnancy in women with a history of peripartum cardiomyopathy may be associated with a further decrease in LV function and can result in clinical deterioration, including death. However, if ventricular function has normalized in women with a history of peripartum cardiomyopathy, the risk may be less. There is an increased risk of venous thromboembolism, and anticoagulation is recommended, especially if ventricular dysfunction is persistent.

5.9. Cardiomyopathy Caused By Iron Overload
Iron overload cardiomyopathy manifests itself as systolic or diastolic dysfunction secondary to increased deposition of iron in the heart and occurs with common genetic disorders such as primary hemochromatosis or with lifetime transfusion requirements as seen in beta-thalassemia major. Hereditary hemochromatosis, an autosomal recessive disorder, is the most common hereditary disease of Northern Europeans, with a prevalence of approximately 5 per 1000. The actuarial survival rates of persons who are homozygous for the mutation of the hemochromatosis gene C282Y have been reported to be 95%, 93%, and 66%, at 5, 10, and 20 years, respectively. Similarly, in patients with thalassemia major, cardiac failure is one of the most frequent causes of death. Chelation therapy, including newer forms of oral chelators, such as deferoxamine, and phlebotomy, have dramatically improved the outcome of hemochromatosis, and the roles of gene therapy, hepcidin, and calcium channel blockers are being actively investigated.

5.10. Amyloidosis
Cardiac amyloidosis involves the deposition of insoluble proteins as fibrils in the heart, resulting in HF. Primary or AL amyloidosis (monoclonal kappa or lambda light chains), secondary amyloidosis (protein A), familial TTR amyloidosis (mutant transthyretin), dialysis-associated amyloidosis (beta-2-microglobulin), or senile TTR amyloidosis (wild-type transthyretin) can affect the heart, but cardiac involvement is primarily encountered in AL and TTR amyloidosis. The disease can be rapidly progressive, and in patients with ventricular septum thickness >15 mm, LVEF <40%, and symptoms of HF, median survival may be <6 months. Cardiac
biomarkers (eg, B-type natriuretic peptide [BNP], cardiac troponin) have been reported to predict response and progression of disease and survival. Three percent to 4% of African Americans carry an amyloidogenic allele of the human serum protein transthyretin (TTR V122I), which appears to increase risk for cardiac amyloid deposition after 65 years of age.

5.11. Cardiac Sarcoidosis
Cardiac sarcoidosis is an underdiagnosed disease that may affect as many as 25% of patients with systemic sarcoidosis. Although most commonly recognized in patients with other manifestations of sarcoidosis, cardiac involvement may occur in isolation and go undetected. Cardiac sarcoidosis may present as asymptomatic LV dysfunction, HF, atrioventricular block, atrial or ventricular arrhythmia, and SCD. Although untested in clinical trials, early use of high-dose steroid therapy may halt or reverse cardiac damage. Cardiac magnetic resonance and cardiac positron emission tomographic scanning can identify cardiac involvement with patchy areas of myocardial inflammation and fibrosis. In the setting of ventricular tachyarrhythmias, patients may require placement of an implantable cardioverter-defibrillator (ICD) for primary prevention of SCD.

5.12. Stress (Takotsubo) Cardiomyopathy
Stress cardiomyopathy is characterized by acute reversible LV dysfunction in the absence of significant CAD, triggered by acute emotional or physical stress. This phenomenon is identified by a distinctive pattern of “apical ballooning,” first described in Japan as takotsubo, and often affects postmenopausal women. A majority of patients have a clinical presentation similar to that of acute coronary syndrome (ACS) and may have transiently elevated cardiac enzymes.

6. Initial and Serial Evaluation of the HF Patient
6.1. Clinical Evaluation
6.1.1. History and Physical Examination: Recommendations
Class I

1. A thorough history and physical examination should be obtained/performed in patients presenting with HF to identify cardiac and noncardiac disorders or behaviors that might cause or accelerate the development or progression of HF. (Level of Evidence: C)

2. In patients with idiopathic DCM, a 3-generational family history should be obtained to aid in establishing the diagnosis of familial DCM. (Level of Evidence: C)

3. Volume status and vital signs should be assessed at each patient encounter. This includes serial assessment of weight, as well as estimates of jugular venous pressure and the presence of peripheral edema or orthopnea. (Level of Evidence: B)

Despite advances in imaging technology and increasing availability of diagnostic laboratory testing, a careful history and physical examination remain the cornerstones in the assessment of patients with HF. The components of a focused history and physical examination for the patient with HF are listed in Table 6. The history provides clues to the etiology of the cardiomyopathy, including the diagnosis of familial cardiomyopathy (defined as ≥2 relatives with idiopathic DCM). Familial syndromes are now recognized to occur in 20% to 35% of patients with apparent idiopathic DCM; thus, a 3-generation family history should be obtained. The history also provides information about the severity of the disease and the patient’s prognosis and identifies opportunities for therapeutic interventions. The physical examination provides information about the severity of illness and allows assessment of volume status and adequacy of perfusion. In advanced HF/pEF, orthopnea and jugular venous pressure are useful findings to detect elevated LV filling pressures.

See Online Data Supplements 5, 6, and 7 for additional data on stress testing and clinical evaluation.

6.1.2. Risk Scoring: Recommendation
Class IIa

1. Validated multivariable risk scores can be useful to estimate subsequent risk of mortality in ambulatory or hospitalized patients with HF. (Level of Evidence: B)

In the course of standard evaluation, clinicians should routinely assess the patient’s potential for adverse outcome, because accurate risk stratification may help guide therapeutic decision making, including a more rapid transition to advanced HF therapies. A number of methods objectively assess risk, including biomarker testing (Section 6.3), as well as a variety of multivariable clinical risk scores (Table 7); these risk scores are for use in ambulatory and hospitalized patients and hospitalization models specifically for patients with HF/pEF have also been described. One well-validated risk score, the Seattle Heart Failure Model, is available in an interactive application on the Internet and provides robust information about risk of mortality in ambulatory patients with HF. For patients hospitalized with acutely decompensated HF, the model developed by ADHERE (Acute Decompensated Heart Failure National Registry) incorporates 3 routinely measured variables on hospital admission (ie, systolic blood pressure, blood urea nitrogen, and serum creatinine) and stratifies subjects into categories with a 10-fold range of crude in-hospital mortality (from 2.1% to 21.9%). Notably, clinical risk scores have not performed as well in estimating risk of hospital readmission. For this purpose, biomarkers such as natriuretic peptides hold considerable promise (Section 6.3).

See Online Data Supplement 8 for additional data on clinical evaluation risk scoring.

6.2. Diagnostic Tests: Recommendations
Class I

1. Initial laboratory evaluation of patients presenting with HF should include complete blood count,
urinalysis, serum electrolytes (including calcium and magnesium), blood urea nitrogen, serum creatinine, glucose, fasting lipid profile, liver function tests, and thyroid-stimulating hormone. *(Level of Evidence: C)*

2. Serial monitoring, when indicated, should include serum electrolytes and renal function. *(Level of Evidence: C)*

3. A 12-lead ECG should be performed initially on all patients presenting with HF. *(Level of Evidence: C)*

---

Class IIa

1. Screening for hemochromatosis or HIV is reasonable in selected patients who present with HF. *(Level of Evidence: C)*

2. Diagnostic tests for rheumatologic diseases, amyloidosis, or pheochromocytoma are reasonable in patients presenting with HF in whom there is a clinical suspicion of these diseases. *(Level of Evidence: C)*
6.3. Biomarkers: Recommendations

A. Ambulatory/Outpatient

Class I

1. In ambulatory patients with dyspnea, measurement of BNP or N-terminal pro-B-type natriuretic peptide (NT-proBNP) is useful to support clinical decision making regarding the diagnosis of HF, especially in the setting of clinical uncertainty. (Level of Evidence: A)

2. Measurement of BNP or NT-proBNP is useful for establishing prognosis or disease severity in chronic HF. (Level of Evidence: A)

Class IIa

1. BNP- or NT-proBNP–guided HF therapy can be useful to achieve optimal dosing of GDMT in select clinically euvolemic patients followed in a well-structured HF disease management program. (Level of Evidence: B)

Class IIb

1. The usefulness of serial measurement of BNP or NT-proBNP to reduce hospitalization or mortality in patients with HF is not well established. (Level of Evidence: B)

2. Measurement of other clinically available tests such as biomarkers of myocardial injury or fibrosis may be considered for additive risk stratification in patients with chronic HF. (Level of Evidence: B)

B. Hospitalized/Acute

Class I

1. Measurement of BNP or NT-proBNP is useful to support clinical judgment for the diagnosis of acutely decompensated HF, especially in the setting of uncertainty for the diagnosis. (Level of Evidence: A)

2. Measurement of BNP or NT-proBNP and/or cardiac troponin is useful for establishing prognosis or disease severity in acutely decompensated HF. (Level of Evidence: A)

Class IIb

1. The usefulness of BNP- or NT-proBNP–guided therapy for acutely decompensated HF is not well established. (Level of Evidence: C)

2. Measurement of other clinically available tests such as biomarkers of myocardial injury or fibrosis may be considered for additive risk stratification in patients with acutely decompensated HF. (Level of Evidence: A)

In addition to routine clinical laboratory tests, other biomarkers are gaining greater attention for their utility in HF management. These biomarkers may reflect various pathophysiological aspects of HF, including myocardial wall stress, hemodynamic abnormalities, inflammation, myocyte injury, neurohormonal upregulation, and myocardial remodeling, as well as extracellular matrix turnover. Thus, these biomarkers are potentially powerful adjuncts to current standards for the diagnosis, prognosis, and treatment of acute and chronic HF.
6.3.1. Natriuretic Peptides: BNP or NT-proBNP

BNP or its amino-terminal cleavage equivalent (NT-proBNP) is derived from a common 108-amino acid precursor peptide (proBNP108) that is generated by cardiomycocytes in the context of numerous triggers, most notably myocardial stretch. Following several steps of processing, BNP and NT-proBNP are released from the cardiomycocyte, along with variable amounts of proBNP108, the latter of which is detected by all assays that measure either “BNP” or “NT-proBNP.”

Assays for BNP and NT-proBNP have been increasingly used to establish the presence and severity of HF. In general, BNP and NT-proBNP values are reasonably correlated, and either can be used in patient care settings as long as their respective absolute values and cut points are not used interchangeably. BNP and NT-proBNP are useful to support clinical judgment for the diagnosis or exclusion of HF, in the setting of chronic ambulatory HF217–223 or acute decompensated HF224–226; the value of natriuretic peptide testing is particularly significant when the etiology of dyspnea is unclear.

Although lower values of BNP or NT-proBNP exclude the presence of HF and higher values have reasonably high positive predictive value to diagnose HF, clinicians should be aware that elevated plasma levels for both natriuretic peptides have been associated with a wide variety of cardiac and noncardiac causes (Table 8).228–231

BNP and NT-proBNP levels improve with treatment of chronic HF222,223,225 with lowering of levels over time in general, correlating with improved clinical outcomes.232–234 Thus, BNP or NT-proBNP “guided” therapy has been studied against standard care without natriuretic peptide measurement to determine whether guided therapy renders superior achievement of GDMT in patients with HF. However, RCTs have yielded inconsistent results.

The positive and negative natriuretic peptide–guided therapy trials differ primarily in their study populations, with successful trials enrolling younger patients and only those with HFpEF. In addition, a lower natriuretic peptide goal and/or a substantial reduction in natriuretic peptides during treatment are consistently present in the positive “guided” therapy trials.235 Although most trials examining the strategy of biomarker “guided” HF management were small and underpowered, 2 comprehensive meta-analyses concluded that BNP-guided therapy reduces all-cause mortality in patients with chronic HF compared with usual clinical care,231,232 especially in patients <75 years of age. This survival benefit may be attributed to increased achievement of GDMT. In some cases, BNP or NT-proBNP levels may not be easily modifiable. If the BNP or NT-proBNP value does not fall after aggressive HF care, risk for death or hospitalization for HF is significant. On the other hand, some patients with advanced HF have normal BNP or NT-proBNP levels or have falsely low BNP levels because of obesity and HFpEF. All of these patients should still receive appropriate GDMT.

6.3.2. Biomarkers of Myocardial Injury: Cardiac Troponin T or I

Abnormal concentrations of circulating cardiac troponin are found in patients with HF, often without obvious myocardial ischemia and frequently in those without underlying CAD. This suggests ongoing myocyte injury or necrosis in these patients.238–241 In chronic HF, elaboration of cardiac troponins is associated with impaired hemodynamics,238 progressive LV dysfunction,239 and increased mortality rates.238–241,247 Similarly, in patients with acute decompensated HF, elevated cardiac troponin levels are associated with worse clinical outcomes and mortality235,237,253; decrease in troponin levels over time with treatment is associated with a better prognosis than persistent elevation in patients with chronic238 or acute HF.239 Given the tight association with ACS and troponin elevation as well as the link between MI and the development of acute HF,239 the measurement of troponin I or T should be routine in patients presenting with acutely decompensated HF syndromes.

6.3.3. Other Emerging Biomarkers

Besides natriuretic peptides or troponins, multiple other biomarkers, including those reflecting inflammation, oxidative stress, neurohormonal disarray, and myocardial and matrix remodeling, have been widely examined for their prognostic value in HF. Biomarkers of myocardial fibrosis, soluble ST2 and galectin-3 are not only predictive of hospitalization and death in patients with HF but also additive to natriuretic peptide levels in their prognostic value. Markers of renal injury may also offer additional prognostic value because renal function or injury may be involved in the pathogenesis, progression, decompensation, or complications in chronic or acute decompensated HF.242–247 Strategies that combine multiple biomarkers may ultimately prove beneficial in guiding HF therapy in the future.

See Table 9 for a summary of recommendations from this section.

6.4. Noninvasive Cardiac Imaging: Recommendations

See Table 10 for a summary of recommendations from this section.
Class I

1. Patients with suspected or new-onset HF, or those presenting with acute decompensated HF, should undergo a chest x-ray to assess heart size and pulmonary congestion and to detect alternative cardiac, pulmonary, and other diseases that may cause or contribute to the patient’s symptoms. (Level of Evidence: C)

2. A 2-dimensional echocardiogram with Doppler should be performed during initial evaluation of patients presenting with HF to assess ventricular function, size, wall thickness, wall motion, and valve function. (Level of Evidence: C)

3. Repeat measurement of EF and measurement of the severity of structural remodeling are useful to provide information in patients with HF who have had a significant change in clinical status; who have experienced or recovered from a clinical event; or who have received treatment, including GDMT, that might have had a significant effect on cardiac function; or who may be candidates for device therapy. (Level of Evidence: C)

Class IIa

1. Noninvasive imaging to detect myocardial ischemia and viability is reasonable in patients presenting with de novo HF, who have known CAD and no angina, unless the patient is not eligible for revascularization of any kind. (Level of Evidence: C)

2. Viability assessment is reasonable in select situations when planning revascularization in HF patients with CAD.281–285 (Level of Evidence: B)

3. Radionuclide ventriculography or magnetic resonance imaging can be useful to assess LVEF and volume when echocardiography is inadequate. (Level of Evidence: C)

4. Magnetic resonance imaging is reasonable when assessing myocardial infiltrative processes or scar burden.286–288 (Level of Evidence: B)

Class III: No Benefit

1. Routine repeat measurement of LV function assessment in the absence of clinical status change or treatment interventions should not be performed.289,290 (Level of Evidence: B)
The chest x-ray is important for the evaluation of patients presenting with signs and symptoms of HF because it assesses cardiomegaly and pulmonary congestion and may reveal alternative causes, cardiopulmonary or otherwise, of the patient’s symptoms. Apart from congestion, however, other findings on chest x-ray are associated with HF only in the context of clinical presentation. Cardiomegaly may be absent in HF. A chest x-ray may also show other cardiac chamber enlargement, increased pulmonary venous pressure, interstitial or alveolar edema, valvular or pericardial calcification, or coexisting thoracic diseases. Considering its low sensitivity and specificity, the chest x-ray should not be the sole determinant of the specific cause of HF. Moreover, a supine chest x-ray has limited value in acute decompensated HF.

Although a complete history and physical examination are important first steps, the most useful diagnostic test in the evaluation of patients with or at risk for HF (eg, postacute MI) is a comprehensive 2-dimensional echocardiogram; coupled with Doppler flow studies, the transthoracic echocardiogram can identify abnormalities of myocardium, heart valves, and pericardium. Echocardiography can reveal subclinical HF and predict risk of subsequent events. Use of echocardiograms in patients with suspected HF improves disease identification and provision of appropriate medical care.

Echocardiographic evaluation should address whether LVEF is reduced, LV structure is abnormal, and other structural abnormalities are present that could account for the clinical presentation. This information should be quantified, including numerical estimates of EF measurement, ventricular dimensions, wall thickness, calculations of ventricular volumes, and evaluation of chamber geometry and regional wall motion. Documentation of LVEF is an HF quality-of-care performance measure. Right ventricular size and function as well as atrial size and dimensions should also be measured. All valves should be evaluated for anatomic and flow abnormalities. Secondary changes, particularly the severity of mitral and tricuspid valve insufficiency, should be determined. Noninvasive hemodynamic data constitute important additional information. Mitral valve inflow pattern, pulmonary venous inflow pattern, and mitral annular velocity provide data about LV filling and left atrial pressure. The tricuspid valve regurgitant gradient, coupled with measurement of inferior vena cava diameter and its response during respiration, provides estimates of systolic pulmonary artery pressure and central venous pressure. Many of these abnormalities are prognostically important and can be present without manifest HF.

Serial echocardiographic evaluations are useful because evidence of cardiac reverse remodeling can provide important information in patients who have had a change in clinical status or have experienced or recovered from an event or treatment that affects cardiac function. However, the routine repeat assessment of ventricular function in the absence of changing clinical status or a change in treatment intervention is not indicated.

The preference for echocardiography as an imaging modality is due to its widespread availability and lack of ionizing radiation; however, other imaging modalities may be of use. Magnetic resonance imaging assesses LV volume and EF measurements at least as accurately as echocardiography. However, additional information about myocardial perfusion, viability, and fibrosis from magnetic resonance imaging can help identify HF etiology and assess prognosis. Magnetic resonance imaging provides high anatomical resolution of all aspects of the heart and surrounding structure, leading to its recommended use in known or suspected congenital heart diseases. Cardiac computed tomography can also provide accurate assessment of cardiac structure and function, including the coronary arteries. An advantage of cardiac computed tomography over echocardiography may be its ability to characterize the myocardium, but studies have yet to demonstrate the importance of this factor. Reports of cardiac computed tomography in patients with suspected HF are limited. Furthermore, both cardiac computed tomography and magnetic resonance imaging lose accuracy with high heart rates. Radionuclide ventriculography may also be used for evaluation of cardiac function when other tests are unavailable or inadequate. However, as a planar technique, radionuclide ventriculography cannot directly assess valvular structure, function, or ventricular wall thickness; it may be more useful for assessing LV volumes in patients with significant baseline wall motion abnormalities or distorted geometry. Ventriculography is highly reproducible. Single photon emission computed tomography or positron emission tomography scans are not primarily used to determine LV systolic global and regional function unless these parameters are quantified from the resultant images during myocardial perfusion and/or viability assessment. Candidates for coronary revascularization who present with a high suspicion for obstructive CAD should undergo coronary angiography. Stress nuclear imaging or echocardiography may be an acceptable option for assessing ischemia in patients presenting with HF who have known CAD and no angina unless they are ineligible for revascularization.

Although the results of the STICH (Surgical Treatment for Ischemic Heart Failure) trial have cast doubt on the role of myocardial viability assessment to determine the mode of therapy, the data are nevertheless predictive of a positive outcome. When these data are taken into consideration with multiple previous studies demonstrating the usefulness of this approach, it becomes reasonable to recommend viability assessment when treating patients with HF who have known CAD.

6.5. Invasive Evaluation: Recommendations
See Table 11 for a summary of recommendations from this section.

Class I

1. Invasive hemodynamic monitoring with a pulmonary artery catheter should be performed to guide therapy in patients who have respiratory distress or clinical evidence of impaired perfusion in whom the adequacy or excess of intracardiac filling pressures cannot be determined from clinical assessment. (Level of Evidence: C)

COR indicates Class of Recommendation; HF, heart failure; and LOE, Level of Evidence.

**Class IIIa**

1. Invasive hemodynamic monitoring can be useful for carefully selected patients with acute HF who have persistent symptoms despite empiric adjustment of standard therapies and
   a. whose fluid status, perfusion, or systemic or pulmonary vascular resistance is uncertain;
   b. whose systolic pressure remains low, or is associated with symptoms, despite initial therapy;
   c. whose renal function is worsening with therapy;
   d. who require parenteral vasoactive agents; or
   e. who may need consideration for MCS or transplantation. (Level of Evidence: C)

2. When ischemia may be contributing to HF, coronary arteriography is reasonable for patients eligible for revascularization. (Level of Evidence: C)

3. Endomyocardial biopsy can be useful in patients presenting with HF when a specific diagnosis is suspected that would influence therapy. (Level of Evidence: C)

**Class III: No Benefit**

1. Routine use of invasive hemodynamic monitoring is not recommended in normotensive patients with acute decompensated HF and congestion with symptomatic response to diuretics and vasodilators.306 (Level of Evidence: B)

**Class III: Harm**

1. Endomyocardial biopsy should not be performed in the routine evaluation of patients with HF. (Level of Evidence: C)

6.5.1. Right-Heart Catheterization

There has been no established role for routine or periodic invasive hemodynamic measurements in the management of HF. Most drugs used for the treatment of HF are prescribed on the basis of their ability to improve symptoms or survival rather than their effect on hemodynamic variables. The initial and target doses of these drugs are generally selected on the basis of controlled trial experience rather than changes produced in cardiac output or pulmonary capillary wedge pressure. Hemodynamic monitoring is indicated in patients with clinically indeterminate volume status and those refractory to initial therapy, particularly if intracardiac filling pressures and cardiac output are unclear. Patients with clinically significant hypotension (systolic blood pressure typically <90 mm Hg or symptomatic low systolic blood pressure) and/or worsening renal function during initial therapy might also benefit from invasive hemodynamic measurements.305,306 Patients being considered for cardiac transplantation or placement of an MCS device are also candidates for complete right-heart catheterization, including an assessment of pulmonary vascular resistance, a necessary part of the initial transplantation evaluation. Invasive hemodynamic monitoring should be performed in patients with 1) presumed cardiogenic shock requiring escalating pressor therapy and consideration of MCS; 2) severe clinical decompensation in which therapy is limited by uncertain contributions of elevated filling pressures, hypoperfusion, and vascular tone; 3) apparent dependence on intravenous inotropic infusions after initial clinical improvement; or 4) persistent severe symptoms despite adjustment of recommended therapies. On the other hand, routine use of invasive hemodynamic monitoring is not recommended in normotensive patients with acute decompensated HF who have a symptomatic response to diuretics and vasodilators. This reinforces the concept that right-heart catheterization is best reserved for those situations where a specific clinical or therapeutic question needs to be addressed.

6.5.2. Left-Heart Catheterization

Left-heart catheterization or coronary angiography is indicated for patients with HF and angina and may be useful for those patients without angina but with LV dysfunction. Invasive coronary angiography should be used in accordance with the ACCF/AHA coronary artery bypass graft (CABG) and percutaneous coronary intervention guidelines10,12 and should only be performed in patients who are potentially eligible for revascularization.307–309 In patients with known CAD and angina or with significant ischemia diagnosed by ECG or noninvasive testing and impaired ventricular function, coronary angiography is indicated. Among those without a prior diagnosis, CAD should be considered as a potential etiology of impaired LV function and should be excluded wherever possible. Coronary angiography may be considered in these circumstances to detect and localize large-vessel coronary obstructions. In patients in whom CAD has been excluded as
the cause of LV dysfunction, coronary angiography is generally not indicated unless a change in clinical status suggests interim development of ischemic disease.

6.5.3. Endomyocardial Biopsy
Endomyocardial biopsy can be useful when seeking a specific diagnosis that would influence therapy, and biopsy should thus be considered in patients with rapidly progressive clinical HF or worsening ventricular dysfunction that persists despite appropriate medical therapy. Endomyocardial biopsy should also be considered in patients suspected of having acute cardiac rejection status after heart transplantation or having myocardial infiltrative processes. A specific example is to determine chemotherapy for primary cardiac amyloidosis. Additional other indications for endomyocardial biopsy include in patients with rapidly progressive and unexplained cardiomyopathy, those in whom active myocarditis, especially giant cell myocarditis, is being considered. Routine endomyocardial biopsy is not recommended in all cases of HF, given limited diagnostic yield and the risk of procedure-related complications.

See Online Data Supplement 10 for additional data on biopsy.

7. Treatment of Stages A to D

7.1. Stage A: Recommendations

Class I

1. Hypertension and lipid disorders should be controlled in accordance with contemporary guidelines to lower the risk of HF (Level of Evidence: A)

2. Other conditions that may lead to or contribute to HF, such as obesity, diabetes mellitus, tobacco use, and known cardiotoxic agents, should be controlled or avoided. (Level of Evidence: C)

7.1.1. Recognition and Treatment of Elevated Blood Pressure
The lifetime risk for development of hypertension is considerable and represents a major public health issue. Elevated blood pressure is a major risk factor for the development of both HFpEF and HFrEF; a risk that extends across all age ranges. Long-term treatment of both systolic and diastolic hypertension has been shown to reduce the risk of incident HF by approximately 50%. Treatment of hypertension is particularly beneficial in older patients. One trial of a diuretic-based program demonstrated a number needed to treat of 52 to prevent 1 HF event in 2 years. In another study, elderly patients with a history or ECG evidence of prior MI had a >80% risk reduction for incident HF with aggressive blood pressure control. Given the robust outcomes with blood pressure reduction, clinicians should lower both systolic and diastolic blood pressure in accordance with published guidelines.

Choice of antihypertensive therapy should also follow guidelines, with specific options tailored to concomitant medical problems, such as diabetes mellitus or CAD. Diuretic-based antihypertensive therapy has repeatedly been shown to prevent HF in a wide range of patients; ACE inhibitors, ARBs, and beta blockers are also effective. Data are less clear for calcium antagonists and alpha blockers in reducing the risk for incident HF.

7.1.2. Treatment of Dyslipidemia and Vascular Risk
Patients with known atherosclerotic disease are likely to develop HF. Clinicians should seek to control vascular risk factors in such patients according to guidelines. Aggressive treatment of hyperlipidemia with statins reduces the likelihood of HF in at-risk patients. Long-term treatment with ACE inhibitors in similar patients may also decrease the risk of HF.

7.1.3. Obesity and Diabetes Mellitus
Obesity and overweight have been repeatedly linked to an increased risk for HF. Presumably, the link between obesity and risk for HF is explained by the clustering of risk factors for heart disease in those with elevated BMI (ie, the metabolic syndrome). Similarly, insulin resistance, with or without diabetes mellitus, is also an important risk factor for the development of HF.

Diabetes mellitus is an especially important risk factor for women and may, in fact, triple the risk for developing HF. Dyshyperglycemia appears to be directly linked to risk, with Hba1c concentrations powerfully predicting incident HF. Those with Hba1c >10.5% had a nearly 4-fold increase in the risk for HF compared with those with a value of <6.5%. Current consensus advocates that clinicians should make every effort to control hyperglycemia, although such control has not yet been shown to reduce the subsequent risk of HF. Additionally, standard therapies for diabetes mellitus, such as use of ACE inhibitors or ARBs, can prevent the development of other risk factors for HF, such as renal dysfunction, and may themselves directly lower the likelihood of HF. Although risk models for the development of incident HF in patients with diabetes mellitus have been developed, their prospective use to reduce risk has not been validated. Despite the lack of supportive, prospective, randomized data, consensus exists that risk factor recognition and modification are vital for the prevention of HF among at-risk patients (eg, obese patients or patients with diabetes mellitus).

7.1.4. Recognition and Control of Other Conditions That May Lead to HF
A substantial genetic risk exists in some patients for the development of HF. As noted in Section 6.1, obtaining a 3-generation family history of HF is recommended. Adequate therapy of AF is advisable, given a clear association between uncontrolled heart rate and development of HF. Many therapeutic agents can exert important cardiotoxic effects, with consequent risk for HF, and clinicians should be aware of such risk. For example, cardiotoxic chemotherapy regimens (particularly anthracycline based) and trastuzumab may increase the risk for HF in certain patients; it may be reasonable to evaluate those who are receiving (or who have received) such agents for LV dysfunction. The use of advanced echocardiographic techniques or biomarkers to identify increased HF risk in those receiving chemotherapy may be useful but remain unvalidated as yet.

Tobacco use is strongly associated with risk for incident HF and patients should be strongly advised about the hazards of smoking, with attendant efforts at quitting. Cocaine and amphetamines are anecdotally but strongly associated with HF, and their avoidance is mandatory. Although it is recognized that alcohol consumption is associated with subsequent
development of HF, there is some uncertainty about the amount of alcohol ingested and the likelihood of developing HF, and there may be sex differences as well. Nevertheless, the heavy use of alcohol has repeatedly been associated with heightened risk for development of HF. Therefore, patients should be counseled about their alcohol intake.

Although several epidemiological studies have revealed an independent link between risk for incident HF and biomarkers such as natriuretic peptides, highly sensitive troponin, and measures of renal function such as creatinine, phosphorus, urinary albumin, or albumin-creatinine ratio, it remains unclear whether the risk for HF reflected by any of these biomarkers is modifiable. Although routine screening with BNP before echocardiography may be a cost-effective strategy to identify high-risk patients, routine measurement of biomarkers in stage A patients is not yet justified.

See Online Data Supplement 11 for additional data on stage A HF.

7.2. Stage B: Recommendations

See Table 12 for a summary of recommendations from this section.

Class I

1. In all patients with a recent or remote history of MI or ACS and reduced EF, ACE inhibitors should be used to prevent symptomatic HF and reduce mortality. In patients intolerant of ACE inhibitors, ARBs are appropriate unless contraindicated. (Level of Evidence: A)

2. In all patients with a recent or remote history of MI or ACS and reduced EF, evidence-based beta blockers should be used to reduce mortality. (Level of Evidence: B)

3. In all patients with a recent or remote history of MI or ACS, statins should be used to prevent symptomatic HF and cardiovascular events. (Level of Evidence: A)

4. In patients with structural cardiac abnormalities, including LV hypertrophy, in the absence of a history of MI or ACS, blood pressure should be controlled in accordance with clinical practice guidelines for hypertension to prevent symptomatic HF. (Level of Evidence: A)

5. ACE inhibitors should be used in all patients with a reduced EF to prevent symptomatic HF, even if they do not have a history of MI. (Level of Evidence: A)

6. Beta blockers should be used in all patients with a reduced EF to prevent symptomatic HF, even if they do not have a history of MI. (Level of Evidence: C)

Class IIa

1. To prevent sudden death, placement of an ICD is reasonable in patients with asymptomatic ischemic cardiomyopathy who are at least 40 days post-MI, have an LVEF of 30% or less, are on appropriate medical therapy, and have reasonable expectation of survival with a good functional status for more than 1 year. (Level of Evidence: B)

Class III: Harm

1. Nondihydropyridine calcium channel blockers with negative inotropic effects may be harmful in asymptomatic patients with low LVEF and no symptoms of HF after MI. (Level of Evidence: C)

Patients with reduced LVEF may not have HF symptoms and are most often identified during an evaluation for another disorder (eg, abnormal heart sounds, abnormal ECG, abnormal chest x-ray, hypertension or hypotension, an arrhythmia, acute MI, or pulmonary or systemic thromboembolic event). However, the cost-effectiveness of routine periodic population screening for asymptomatic reduced LVEF is not recommended at this time. Echocardiographic evaluation should be performed in selected patients who are at high risk of reduced LVEF (eg, those with a strong family history of cardiomyopathy, long-standing

ACE indicates angiotensin-converting enzyme; ARB, angiotensin-receptor blocker; COR, Class of Recommendation; EF, ejection fraction; GDMT, guideline-directed medical therapy; HF, heart failure; ICD, implantable cardioverter-defibrillator; LOE, Level of Evidence; LVEF, left ventricular ejection fraction; MI, myocardial infarction; and N/A, not available.
hypertension, previous MI, or those receiving cardiotoxic therapies). In addition, it should be acknowledged that many adults may have asymptomatic valvular abnormalities or congenital heart lesions that if unrecognized could lead to the development of clinical HF. Although these asymptomatic patients are in stage B as well, the management of valvular and congenital heart disease is beyond the scope of this guideline.

### 7.2.1. Management Strategies for Stage B

In general, all recommendations for patients with stage A HF also apply to those with stage B HF, particularly with respect to control of blood pressure in the patient with LV hypertrophy and the optimization of lipids with statins. CAD is a major risk factor for the development of HF and a key target for prevention of HF. The 5-year risk of developing HF after acute MI is 7% and 12% for men and women, respectively; for men and women between the ages of 40 and 69 and those >70 years of age, the risk is 22% and 25%, respectively. Current evidence supports the use of ACE inhibitors and (to a lower level of evidence) beta-blocker therapy to impede maladaptive LV remodeling in patients with stage B HF and low LVEF to improve mortality and morbidity. At 3-year follow-up, those patients treated with ACE inhibitors demonstrated combined endpoints of reduced hospitalization or death, a benefit that extended up to a 12-year follow-up. ARBs are reasonable alternatives to ACE inhibitors. In 1 study, losartan reduced adverse outcomes in a population with hypertension, and in another study of patients post-MI with low LVEF, valsartan was equivalent to captopril. Data with beta blockers are less convincing in a population with known CAD, although in 1 trial carvedilol therapy in patients with stage B HF and low LVEF was associated with a 31% relative risk reduction in adverse long-term outcomes. In patients with previously established structural heart disease, the administration of agents known to have negative inotropic properties such as nondihydropyridine calcium channel blockers and certain antiarrhythmics should be avoided.

Elevations in both systolic and diastolic blood pressure are major risk factors for developing LV hypertrophy, another form of stage B. Although the magnitude of benefit varies with the trial selection criteria, target blood pressure reduction, and HF criteria, effective hypertension treatment invariably reduces HF events. Consequently, long-term treatment of both systolic and diastolic hypertension reduces the risk of moving from stage A or B to stage C HF. Several large controlled studies have uniformly demonstrated that optimal blood pressure control decreases the risk of new HF by approximately 50%. It is imperative that strategies to control hypertension be part of any effort to prevent HF.

Clinicians should lower both systolic and diastolic blood pressure in accordance with published guidelines. Target levels of blood pressure lowering depend on major cardiovascular risk factors, (eg, CAD, diabetes mellitus, or renal disease). Thus, when an antihypertensive regimen is devised, optimal control of blood pressure should remain the primary goal, with the choice of drugs determined by the concomitant medical problems.

Diuretic-based antihypertensive therapy has been shown to prevent HF in a wide range of target populations. In refractory hypertensive patients, spironolactone (25 mg) should be considered as an additional agent. Eplerenone, in synergy with enalapril, has also demonstrated reduction in LV mass.

### Table 13. Other ACCF/AHA Guidelines Addressing Patients With Stage B HF

<table>
<thead>
<tr>
<th>Consideration</th>
<th>Reference</th>
</tr>
</thead>
<tbody>

<td>2011 PCI Guideline</td>
</tr>
<tr>
<td>Valve replacement or repair for patients with hemodynamically significant valvular stenosis or regurgitation and no symptoms of HF in accordance with GDMT</td>
<td>2006 VHD Guideline</td>
</tr>
</tbody>
</table>

ACCF indicates American College of Cardiology Foundation; AHA, American Heart Association; CABG, coronary artery bypass graft; GDMT, guideline-directed medical therapy; HF, heart failure; MI, myocardial infarction; PCI, percutaneous coronary intervention; SIHD, stable ischemic heart disease; STEMI, ST-elevation myocardial infarction; UA/NSTEMI, unstable angina/non-ST-elevation myocardial infarction; and VHD, valvular heart disease.

ACE inhibitors and beta blockers are also effective in the prevention of HF. Nevertheless, neither ACE inhibitors nor beta blockers as single therapies are superior to other antihypertensive drug classes, including calcium channel blockers, in the reduction of all cardiovascular outcomes. However, in patients with type 2 diabetes mellitus, ACE inhibitors and ARBs significantly reduced the incidence of HF in patients. In contrast, calcium channel blockers and alpha blockers were less effective in preventing the HF syndrome, particularly in HF/EF.

The Framingham studies have shown a 60% increased risk of death in patients with asymptomatic low LVEF compared with those with normal LVEF; almost half of these patients remained free of HF before their death. MADIT-II (Multicenter Automatic Defibrillator Implantation Trial II) demonstrated a 31% relative risk reduction in all-cause mortality in patients with post-MI with LVEF ≤30% receiving a prophylactic ICD compared with standard of care. These findings provided justification for broad adoption of ICDs for primary prevention of SCD in the post-MI setting with reduced LVEF, even in the absence of HF symptoms, that is, patients in stage B HF.

Several other ACCF/AHA guidelines addressing the appropriate management of patients with stage B—those with cardiac structural abnormalities but no symptoms of HF—are listed in Table 13.

See Online Data Supplement 12 for additional data on stage B HF.

### 7.3. Stage C

See Online Data Supplement 13 for additional data on stage C HF.

#### 7.3.1. Nonpharmacological Interventions

#### 7.3.1.1. Education: Recommendation

Class I

1. Patients with HF should receive specific education to facilitate HF self-care. (Level of Evidence: B)

The self-care regimen for patients with HF is complex and multifaceted. Patients need to understand how to monitor their symptoms and weight fluctuations, restrict their sodium...
intake, take their medications as prescribed, and stay physically active. Education regarding these recommendations is necessary, albeit not always sufficient, to significantly improve outcomes. After discharge, many patients with HF need disease management programs, which are reviewed in Section 11.

A systematic review of 35 educational intervention studies for patients with HF demonstrated that education improved knowledge, self-monitoring, medication adherence, time to hospitalization, and days in the hospital. Patients who receive in-hospital education have higher knowledge scores at discharge and 1 year later when compared with those who did not receive in-hospital education. Data have called into question the survival benefit of discharge education. However, prior data have suggested that discharge education may result in fewer days of hospitalization, lower costs, and lower mortality rates within a 6-month follow-up. Patients educated in all 6 categories of the HF core measures from The Joint Commission were significantly less likely to be readmitted for any cause, including HF. Even a single home-based educational intervention for patients and families has been shown to decrease emergency visits and unplanned hospitalizations in adults with HF.

See Online Data Supplement 14 for additional data on patient nonadherence.

### 7.3.1.2. Social Support

Social support is thought to buffer stress and promote treatment adherence and a healthy lifestyle. Most studies examining the relationship between social support and hospitalization in adults with HF have found that a lack of social support is associated with higher hospitalization rates and mortality risk.

### 7.3.1.3. Sodium Restriction: Recommendation

**Class IIa**

1. Sodium restriction is reasonable for patients with symptomatic HF to reduce congestive symptoms. *(Level of Evidence: C)*

Dietary sodium restriction is commonly recommended to patients with HF and is endorsed by many guidelines. The data on which this recommendation is drawn upon, however, are modest, and variances in protocols, fluid intake, measurement of sodium intake and compliance, and other clinical and therapeutic characteristics among these studies make it challenging to compare data and draw definitive conclusions. Observational data suggest an association between dietary sodium intake with fluid retention and risk for hospitalization. Other studies, however, have signaled a worsening neurohormonal profile with sodium restriction in HF. Sodium homeostasis is altered in patients with HF as opposed to healthy individuals, which may partially explain these trends. In most of these studies, patients were not receiving GDMT; no study to date has evaluated the effects of sodium restriction on neurohormonal activation and outcomes in optimally treated patients with HF. With the exception of 1 observational study that evaluated patients with HF, all other studies have focused on patients with HF. These data are mostly from white patients; when the differences in cardiovascular and renal pathophysiology among races are considered, the effects of sodium restriction in nonwhite patients with HF cannot be ascertained from these studies. To make this more complicated, the 3 RCTs that assessed outcomes with sodium restriction have all shown that lower sodium intake is associated with worse outcomes in patients with HF.

These limitations make it difficult to give precise recommendations about daily sodium intake and whether it should vary with respect to the type of HF (eg, HFpEF vs HFpEF), disease severity (eg, NYHA class), HF-related comorbidities (eg, renal dysfunction), or other characteristics (eg, age or race). Because of the association between sodium intake and hypertension, LV hypertrophy, and cardiovascular disease, the AHA recommendation for restriction of sodium to 1500 mg/d appears to be appropriate for most patients with stage A and B HF. However, for patients with stage C and D HF, currently there is insufficient data to endorse any specific level of sodium intake. Because sodium intake is typically high (>4 g/d) in the general population, clinicians should consider some degree (eg, <3 g/d) of sodium restriction in patients with stage C and D HF for symptom improvement.

### 7.3.1.4. Treatment of Sleep Disorders: Recommendation

**Class IIa**

1. Continuous positive airway pressure can be beneficial to increase LVEF and improve functional status in patients with HF and sleep apnea. *(Level of Evidence: B)*

Sleep disorders are common in patients with HF. A study of adults with chronic HF treated with evidence-based therapies found that 61% had either central or obstructive sleep apnea. Despite having less sleep time and sleep efficiency compared with those without HF, patients with HF, including those with documented sleep disorders, rarely report excessive daytime sleepiness. Thus, a high degree of suspicion for sleep disorders should be maintained for these patients. The decision to refer a patient to a sleep study should be based on clinical judgment.

The primary treatment for obstructive sleep apnea is nocturnal continuous positive airway pressure. In a major trial, continuous positive airway pressure for obstructive sleep apnea was effective in decreasing the apnea–hypopnea index, improving nocturnal oxygenation, increasing LVEF, lowering norepinephrine levels, and increasing the distance walked in 6 minutes; these benefits were sustained for up to 2 years. Smaller studies suggest that continuous positive airway pressure can improve cardiac function, sympathetic activity, and HRQOL in patients with HF and obstructive sleep apnea.

See Online Data Supplement 15 for additional data on the treatment of sleep disorders.

### 7.3.1.5. Weight Loss

Obesity is defined as a BMI ≥30 kg/m². Patients with HF who have a BMI between 30 and 35 kg/m² have lower mortality and hospitalization rates than those with a BMI in the normal range. Weight loss may reflect cachexia caused by the higher total energy expenditure associated with HF compared with that of healthy sedentary subjects. The diagnosis of cardiac cachexia independently predicts a worse prognosis. At the other end of the continuum, morbidly obese patients may have worse outcomes compared with patients within the normal weight range and those who are obese. A U-shaped distribution curve has been suggested in which mortality is greatest in cachectic...
patients; lower in normal, overweight, and mildly obese patients; and higher again in more severely obese patients.400

Although there are anecdotal reports about symptomatic improvement after weight reduction in obese patients with HF,401,402 large-scale clinical trials on the role of weight loss in patients with HF with obesity have not been performed. Because of reports of development of cardiomyopathy, sibutramine is contraindicated in HF.403

7.3.1.6. Activity, Exercise Prescription, and Cardiac Rehabilitation: Recommendations

Class I

1. Exercise training (or regular physical activity) is recommended as safe and effective for patients with HF who are able to participate to improve functional status.404–407 (Level of Evidence: A)

Class IIa

1. Cardiac rehabilitation can be useful in clinically stable patients with HF to improve functional capacity, exercise duration, HRQOL, and mortality.408,409–411 (Level of Evidence: B)

Exercise training in patients with HF is safe and has numerous benefits. Meta-analyses show that cardiac rehabilitation reduces mortality; improves functional capacity, exercise duration, and HRQOL; and reduces hospitalizations.409 Other benefits include improved endothelial function, blunted catecholamine spillover, increased peripheral oxygen extraction, and reduced hospital admission.405,407,410,411

Many RCTs of exercise training in HF have been conducted, but the statistical power of most was low.408 A major trial of exercise and HF randomly assigned 2331 patients (mean EF, 25%; ischemic etiology, 52%) to either exercise training for 3 months or usual care.406 In unadjusted analyses, there was no significant difference at the end of the study in either total mortality or hospitalizations. When adjusted for coronary heart disease risk factors, there was an 11% reduction in all-cause mortality, cardiovascular disease mortality, or hospitalizations (P<0.03) in the exercise training group.406 A meta-analysis demonstrated improved peak oxygen consumption and decreased all-cause mortality with exercise.409

See Online Data Supplement 16 for additional data on cardiac exercise.

7.3.2. Pharmacological Treatment for Stage C HFrEF: Recommendations

Class I

1. Measures listed as Class I recommendations for patients in stages A and B are recommended where appropriate for patients in stage C. (Levels of Evidence: A, B, and C as appropriate)

2. GDMT as depicted in Figure 1 should be the mainstay of pharmacological therapy for HFrEF.108,343,345,346,412–426 (Level of Evidence: A)

Figure 1. Stage C HFrEF: evidence-based, guideline-directed medical therapy. ACEI indicates angiotensin-converting enzyme inhibitor; ARB, angiotensin-receptor blocker; HFrEF, heart failure with reduced ejection fraction; Hydral-Nitrates, hydralazine and isosorbide dinitrate; LOE, Level of Evidence; and NYHA, New York Heart Association.
Diuretics inhibit the reabsorption of sodium or chloride at specific sites in the renal tubules. Bumetanide, furosemide, and torsemide act at the loop of Henle (thus, the term loop diuretics), whereas thiazides, metolazone, and potassium-sparing agents (eg, spironolactone) act in the distal portion of the tubule. Loop diuretics have emerged as the preferred diuretic agents for use in most patients with HF. Thiazide diuretics may be considered in hypertensive patients with HF and mild fluid retention because they confer more persistent antihypertensive effects.

Controlled trials have demonstrated the ability of diuretic drugs to increase urinary sodium excretion and decrease physical signs of fluid retention in patients with HF. In intermediate-term studies, diuretics have been shown to improve symptoms and exercise tolerance in patients with HF, however, diuretic effects on morbidity and mortality are not known. Diuretics are the only drugs used for the treatment of HF that can adequately control the fluid retention of HF. Appropriate use of diuretics is a key element in the success of other drugs used for the treatment of HF. The use of inappropriately low doses of diuretics will result in fluid retention. Conversely, the use of inappropriately high doses of diuretics will lead to volume contraction, which can increase the risk of hypotension and renal insufficiency.

7.3.2.1. Diuretics: Recommendation

Class I

1. Diuretics are recommended in patients with HFrEF who have evidence of fluid retention, unless contraindicated, to improve symptoms. (Level of Evidence: C)

Diuretics are recommended in patients with HFrEF who have evidence of fluid retention, unless contraindicated, to improve symptoms. (Level of Evidence: C)

*Eplerenone, although also a diuretic, is primarily used in chronic HF.
†Higher doses may occasionally be used with close monitoring.
‡See Section 8.4.

HF indicates heart failure; IV, intravenous; and N/A, not applicable.

Diuretic resistance can generally be overcome by the intravenous administration of diuretics (including the use of continuous infusions) or combination of different diuretic classes (eg, metolazone with a loop diuretic). Patients may become unresponsive to high doses of diuretic drugs if they consume large amounts of dietary sodium, are taking agents that can block the effects of diuretics (eg, nonsteroidal anti-inflammatory drugs [NSAIDs], including cyclooxygenase-2 inhibitors or have a significant impairment of renal function or perfusion. Diuretic resistance can generally be overcome by the intravenous administration of diuretics (including the use of continuous infusions) or combination of different diuretic classes (eg, metolazone with a loop diuretic).

7.3.2.2. ACE Inhibitors: Recommendation

Class I

1. ACE inhibitors are recommended in patients with HFrEF and current or prior symptoms, unless
contraindicated, to reduce morbidity and mortality.343,412–414 (Level of Evidence: A)

7.3.2.2.1. ACE Inhibitors: Selection of Patients. ACE inhibitors can reduce the risk of death and reduce hospitalization in HFrEF. The benefits of ACE inhibition were seen in patients with mild, moderate, or severe symptoms of HF and in patients with or without CAD. ACE inhibitors should be prescribed to all patients with HFrEF. Unless there is a contraindication, ACE inhibitors are used together with a beta blocker. Patients should not be given an ACE inhibitor if they have experienced life-threatening adverse reactions (ie, angioedema) during previous medication exposure or if they are pregnant or plan to become pregnant. Clinicians should prescribe an ACE inhibitor with caution if the patient has very low systemic blood pressures (systolic blood pressure <80 mm/Hg), markedly increased serum levels of creatinine (>3 mg/dL), bilateral renal artery stenosis, or elevated levels of serum potassium (>5.0 mEq/L).

7.3.2.2.2. ACE Inhibitors: Initiation and Maintenance. The available data suggest that there are no differences among available ACE inhibitors in their effects on symptoms or survival.414 Treatment with an ACE inhibitor should be initiated at low doses (Table 15), followed by gradual dose increments if lower doses have been well tolerated. Renal function and serum potassium should be assessed within 1 to 2 weeks of initiation of therapy and periodically thereafter, especially in patients with preexisting hypotension, hyponatremia, diabetes mellitus, azotemia, or in those taking potassium supplements. In controlled clinical trials that were designed to evaluate survival, the dose of the ACE inhibitor was not determined by a patient’s therapeutic response but was increased until the predetermined target dose was reached.343,413,414 Clinicians should attempt to use doses that have been shown to reduce the risk of cardiovascular events in clinical trials. If these target doses of an ACE inhibitor cannot be used or are poorly tolerated, intermediate doses should be used with the expectation that there are likely to be only small differences in efficacy between low and high doses. Abrupt withdrawal of treatment with an ACE inhibitor can lead to clinical deterioration and should be avoided.

ACE indicates angiotensin-converting enzyme; ARB, angiotensin-receptor blocker; CR, controlled release; CR/XL, controlled release/extended release; HFrEF, heart failure with reduced ejection fraction; and N/A, not applicable.
7.3.2.3. ACE Inhibitors: Risks of Treatment. The majority of the adverse reactions of ACE inhibitors can be attributed to the 2 principal pharmacological actions of these drugs: those related to angiotensin suppression and those related to kinin potentiation. Other types of adverse effects may also occur (eg, rash and taste disturbances). Up to 20% of patients will experience an ACE inhibitor–induced cough. With the use of ACE inhibitors, particular care should be given to the patient’s volume status, renal function, and concomitant medications (Sections 7.3.2.1 and 7.3.2.9). However, most HF patients (85% to 90%) can tolerate these drugs.

See Online Data Supplement 18 for additional data on ACE inhibitors.

7.3.2.3. ARBs: Recommendations

Class I

1. ARBs are recommended in patients with HFREF or with current or prior symptoms who are ACE inhibitor intolerant, unless contraindicated, to reduce morbidity and mortality. (Level of Evidence: A)

Class IIa

1. ARBs are reasonable to reduce morbidity and mortality as alternatives to ACE inhibitors as first-line therapy for patients with HFREF, especially for patients already taking ARBs for other indications, unless contraindicated. (Level of Evidence: A)

Class IIb

1. Addition of an ARB may be considered in persistent symptomatic patients with HFREF who are already being treated with an ACE inhibitor and a beta blocker in whom an aldosterone antagonist is not indicated or tolerated. (Level of Evidence: A)

Class III: Harm

1. Routine combined use of an ACE inhibitor, ARB, and aldosterone antagonist is potentially harmful for patients with HFREF. (Level of Evidence: C)

ARBs were developed with the rationale that a) angiotensin II production continues in the presence of ACE inhibition, driven through alternative enzyme pathways and b) interference with the renin-angiotensin system without inhibition of kininase would produce all of the benefits of ACE inhibitors while minimizing the risk of adverse reactions to them. However, it is now known that some of the benefits of ACE inhibitors may be related to the accumulation of kinins rather than to the suppression of angiotensin II formation, whereas some of the adverse effects of ACE inhibitors in HF are related to the suppression of angiotensin II formation.

In several placebo-controlled studies, long-term therapy with ARBs produced hemodynamic, neurohormonal, and clinical effects consistent with those expected after interference with the renin-angiotensin system. Reduced hospitalization and mortality have been demonstrated. ACE inhibitors remain the first choice for inhibition of the renin-angiotensin system in systolic HF, but ARBs can now be considered a reasonable alternative.

7.3.2.3.1. ARBs: Selection of Patients. ARBs are used in patients with HFREF who are ACE inhibitor intolerant; an ACE-inhibition intolerance primarily related to cough is the most common indication. In addition, an ARB may be used as an alternative to an ACE inhibitor in patients who are already taking an ARB for another reason, such as hypertension, and who subsequently develop HF. Angioedema occurs in <1% of patients who take an ACE inhibitor, but it occurs more frequently in blacks. Because its occurrence may be life-threatening, clinical suspicion of this reaction justifies the subsequent avoidance of all ACE inhibitors for the lifetime of the patient. ACE inhibitors should not be initiated in any patient with a history of angioedema. Although ARBs may be considered as alternative therapy for patients who have developed angioedema while taking an ACE inhibitor, there are some patients who have also developed angioedema with ARBs, and caution is advised when substituting an ARB in a patient who has had angioedema associated with use of an ACE inhibitor. 

7.3.2.3.2. ARBs: Initiation and Maintenance. When used, ARBs should be initiated with the starting doses shown in Table 15. Many of the considerations with initiation of an ARB are similar to those with initiation of an ACE inhibitor, as discussed previously. Blood pressure (including postural blood pressure changes), renal function, and potassium should be reassessed within 1 to 2 weeks after initiation and followed closely after changes in dose. Patients with systolic blood pressure <80 mmHg, low serum sodium, diabetes mellitus, and impaired renal function merit close surveillance during therapy with inhibitors of the renin angiotensin-aldosterone system. Titration is generally achieved by doubling doses. For stable patients, it is reasonable to add therapy with beta-blocking agents before full target doses of either ACE inhibitors or ARBs are reached.

7.3.2.3.3. ARBs: Risks of Treatment. The risks of ARBs are attributed to suppression of angiotensin stimulation. These risks of hypotension, renal dysfunction, and hyperkalemia are greater when combined with another inhibitor of this neurohormonal axis, such as ACE inhibitors or aldosterone antagonists.

See Online Data Supplement 19 for additional data on ARBs.

7.3.2.4. Beta Blockers: Recommendation

Class I

1. Use of 1 of the 3 beta blockers proven to reduce mortality (eg, bisoprolol, carvedilol, and sustained-release metoprolol succinate) is recommended for all patients with current or prior symptoms of HFREF, unless contraindicated, to reduce morbidity and mortality. (Level of Evidence: A)

Long-term treatment with beta blockers can lessen the symptoms of HF, improve the patient’s clinical status, and enhance the patient’s overall sense of well-being. In addition, like ACE inhibitors, beta blockers can reduce the risk of death and the combined risk of death or hospitalization. These benefits of beta blockers were seen in patients with or without CAD and in patients with or without diabetes mellitus, as well as in women and blacks. The favorable effects
of beta blockers were also observed in patients already taking ACE inhibitors.

Three beta blockers have been shown to be effective in reducing the risk of death in patients with chronic HF EF: bisoprolol and sustained-release metoprolol (succinate), which selectively block beta-1–receptors; and carvedilol, which blocks alpha-1–, beta-1–, and beta-2–receptors. Positive findings with these 3 agents, however, should not be considered a beta-blocker class effect. Bucindolol lacked uniform effectiveness across different populations, and short-acting metoprolol tartrate was less effective in HF clinical trials. Beta-1 selective blocker nebivolol demonstrated a modest reduction in the primary endpoint of all-cause mortality or cardiovascular hospitalization but did not affect mortality alone in an elderly population that included patients with HFpEF.472

7.3.2.4.1. Beta Blockers: Selection of Patients. Beta blockers should be prescribed to all patients with stable HF EF unless they have a contraindication to their use or are intolerant of these drugs. Because of its favorable effects on survival and disease progression, a clinical trial–proven beta blocker should be initiated as soon as HF EF is diagnosed. Even when symptoms are mild or improve with other therapies, beta-blocker therapy is important and should not be delayed until symptoms return or disease progression is documented. Therefore, even if patients have little disability and experience seemingly minimal symptomatic benefit, they should still be treated with a beta blocker to reduce the risks of disease progression, clinical deterioration, and sudden death.117,448,469–471

Patients need not take high doses of ACE inhibitors before initiation of beta-blocker therapy. In patients taking a low dose of an ACE inhibitor, the addition of a beta blocker produces a greater improvement in symptoms and reduction in the risk of death than does an increase in the dose of the ACE inhibitor, even to the target doses used in clinical trials.445,473 In patients with a current or recent history of fluid retention, beta blockers should not be prescribed without diuretics, because diuretics are needed to maintain sodium and fluid balance and prevent the exacerbation of fluid retention that can accompany the initiation of beta-blocker therapy.474 Beta blockers may be considered in patients who have reactive airway disease or asymptomatic bradycardia but should be used cautiously in patients with persistent symptoms of either condition.

7.3.2.4.2. Beta Blockers: Initiation and Maintenance. Treatment with a beta blocker should be initiated at very low doses (Table 15), followed by gradual increments in dose if lower doses have been well tolerated. Patients should be monitored closely for changes in vital signs and symptoms during this uptitration period. Planned increments in the dose of a beta blocker should be delayed until any adverse effects observed with lower doses have disappeared. When such a cautious approach was used, most patients (approximately 85%) enrolled in clinical trials who received beta blockers were able to tolerate short- and long-term treatment with these drugs and achieve the maximum planned trial dose.117,447,448,470 Data show that beta blockers can be safely started before discharge even in patients hospitalized for HF; provided they do not require intravenous inotropic therapy for HF.476 Clinicians should make every effort to achieve the target doses of the beta blockers shown to be effective in major clinical trials. Even if symptoms do not improve, long-term treatment should be maintained to reduce the risk of major clinical events. Abrupt withdrawal of treatment with a beta blocker can lead to clinical deterioration and should be avoided.477

7.3.2.4.3. Beta Blockers: Risks of Treatment. Initiation of treatment with a beta blocker may produce 4 types of adverse reactions that require attention and management: fluid retention and worsening HF; fatigue; bradycardia or heart block; and hypotension. The occurrence of fluid retention or worsening HF is not generally a reason for the permanent withdrawal of treatment. Such patients generally respond favorably to intensification of conventional therapy, and once treated, they remain excellent candidates for long-term treatment with a beta blocker. The slowing of heart rate and cardiac conduction produced by beta blockers is generally asymptomatic and thus requires no treatment; however, if the bradycardia is accompanied by dizziness or lightheadedness or if second- or third-degree heart block occurs, clinicians should decrease the dose of the beta blocker. Clinicians may minimize the risk of hypotension by administering the beta blocker and ACE inhibitor at different times during the day. Hypotensive symptoms may also resolve after a decrease in the dose of diuretics in patients who are volume depleted. If hypotension is accompanied by other clinical evidence of hypoperfusion, beta-blocker therapy should be decreased or discontinued pending further patient evaluation. The symptom of fatigue is multifactorial and is perhaps the hardest symptom to address with confidence. Although fatigue may be related to beta blockers, other causes of fatigue should be considered, including sleep apnea, overdiuresis, or depression.

See Online Data Supplement 20 for additional data on beta blockers.

7.3.2.5. Aldosterone Receptor Antagonists: Recommendations

Class I

1. Aldosterone receptor antagonists (or mineralocorticoid receptor antagonists) are recommended in patients with NYHA class II–IV HF and who have LVEF of 35% or less, unless contraindicated, to reduce morbidity and mortality. Patients with NYHA class II HF should have a history of prior cardiovascular hospitalization or elevated plasma natriuretic peptide levels to be considered for aldosterone receptor antagonists. Creatinine should be 2.5 mg/dL or less in men or 2.0 mg/dL or less in women (or estimated glomerular filtration rate >30 mL/min/1.73 m2), and potassium should be less than 5.0 mEq/L. Careful monitoring of potassium, renal function, and diuretic dosing should be performed at initiation and closely followed thereafter to minimize risk of hyperkalemia and renal insufficiency.425,426,478 (Level of Evidence: A)

2. Aldosterone receptor antagonists are recommended to reduce morbidity and mortality following an acute MI in patients who have LVEF of 40% or less who develop symptoms of HF or who have a history of diabetes mellitus, unless contraindicated.448 (Level of Evidence: B)
EF.426,446

a wider range of patients with HF and LVEF <35%. Eplerenone has been shown to reduce all-cause mortality as well as a reduced risk of SCD and HF hospitalizations in patients with chronic HF Failure) had an estimated glomerular filtration rate of <60 mL/min/1.73 m².

Note also that the entry criteria for the EMPHASIS-HF trial were age of at least 55 years, NYHA class II ≥ ≥ 1.7 mg/dL. 425,446

Adapted from Butler et al.481

Class III: Harm

1. Inappropriate use of aldosterone receptor antagonists is potentially harmful because of life-threatening hyperkalemia or renal insufficiency when serum creatinine is greater than 2.5 mg/dL in men or greater than 2.0 mg/dL in women (or estimated glomerular filtration rate <30 mL/min/1.73 m²), and/or potassium greater than 5.0 mEq/L. 479,480 (Level of Evidence: B)

The landmark RALES trial (Randomized Aldactone Evaluation Study) 425 showed a 30% reduction in all-cause mortality as well as a reduced risk of SCD and HF hospitalizations with the use of spironolactone in patients with chronic HF EF 35%. Eplerenone has been shown to reduce all-cause deaths, cardiovascular deaths, or HF hospitalizations in a wider range of patients with HF EF. 426,446

7.3.2.5.1. Aldosterone Receptor Antagonists: Selection of Patients. Clinicians should strongly consider the addition of the aldosterone receptor antagonists spironolactone or eplerenone for all patients with HF EF who are already on ACE inhibitors (or ARBs) and beta blockers. Although the entry criteria for the trials of aldosterone receptor antagonists excluded patients with a creatinine >2.5 mg/dL, the majority of patients had much lower creatinine (95% of patients had creatinine ≤1.7 mg/dL). 425,426,446

In contrast, one third of patients in EMPHASIS-HF (Eplerenone in Mild Patients Hospitalization and Survival Study in Heart Failure) had an estimated glomerular filtration rate of <60 mL/min/1.73 m². 426 Note also that the entry criteria for the EMPHASIS-HF trial were age of at least ≥55 years, NYHA class II symptoms, and an EF of no more than 30% (or, if >30% to 35%, a QRS duration of >130 ms on ECG). To minimize the risk of life-threatening hyperkalemia in euvolemic patients with HF EF, patients should have initial serum creatinine <2.5 mg/dL (or an estimated glomerular filtration rate >30 mL/min/1.73 m²) without recent worsening and serum potassium <5.0 mEq/L without a history of severe hyperkalemia. Careful patient selection and risk assessment with availability of close monitoring is essential in initiating the use of aldosterone receptor antagonists.

7.3.2.5.2. Aldosterone Receptor Antagonists: Initiation and Maintenance. Spironolactone should be initiated at a dose of 12.5 to 25 mg daily, while eplerenone should be initiated at a dose of 25 mg/d, increasing to 50 mg daily. For those with concerns of hyperkalemia or marginal renal function (estimated glomerular filtration rate 30 to 49 mL/min/1.73 m²), an initial regimen of every-other-day dosing is advised (Table 16). After initiation of aldosterone receptor antagonists, potassium supplementation should be discontinued (or reduced and carefully monitored in those with a history of hypokalemia; Table 17), and patients should be counseled to avoid foods high in potassium and NSAIDs. Potassium levels and renal function should be rechecked within 2 to 3 days and again at 7 days after initiation of an aldosterone receptor antagonist. Subsequent monitoring should be dictated by the general clinical stability of renal function and fluid status but should occur at least monthly for the first 3 months and every 3 months thereafter. The addition or an increase in dosage of ACE inhibitors or ARBs should trigger a new cycle of monitoring.

There are limited data to support or refute that spironolactone and eplerenone are interchangeable. The perceived difference between eplerenone and spironolactone is the selectivity of aldosterone receptor antagonism and not the effectiveness of blocking mineralocorticoid activity. In RALES, there was

*After dose initiation for K+, increase ≤6.0 mEq/L or worsening renal function, hold until K+ <5.0 mEq/L. Consider restarting reduced dose after confirming resolution of hyperkalemia/renal insufficiency for at least 72 h.

eGFR indicates estimated glomerular filtration rate; and, K+, potassium.

Table 17. Strategies to Minimize the Risk of Hyperkalemia in Patients Treated With Aldosterone Antagonists

1. Impaired renal function is a risk factor for hyperkalemia during treatment with aldosterone antagonists. The risk of hyperkalemia increases progressively when serum creatinine is >1.6 mg/dL.* In elderly patients or others with low muscle mass in whom serum creatinine does not accurately reflect glomerular filtration rate, determination that glomerular filtration rate or creatinine clearance is >30 mL/min/1.73 m² is recommended.

2. Aldosterone antagonists would not ordinarily be initiated in patients with baseline serum potassium >5.0 mEq/L.

3. An initial dose of spironolactone of 12.5 mg or eplerenone 25 mg is typical, after which the dose may be increased to spironolactone 25 mg or eplerenone 50 mg if appropriate.

4. The risk of hyperkalemia is increased with concomitant use of higher doses of ACE inhibitors (captopril ≥75 mg daily; enalapril or lisinopril ≥10 mg daily).

5. In most circumstances, potassium supplements are discontinued or reduced when initiating aldosterone antagonists.

6. Close monitoring of serum potassium is required; potassium levels and renal function are most typically checked in 3 d and at 1 wk after initiating therapy and at least monthly for the first 3 mo.

*Although the entry criteria for the trials of aldosterone antagonists included creatinine <2.5 mg/dL, the majority of patients had much lower creatinine; in 1 trial, 425 95% of patients had creatinine ≤1.7 mg/dL.

ACE indicates angiotensin-converting enzyme.
increased incidence (10%) of gynecomastia or breast pain with use of spironolactone (a nonselective antagonist). The incidence of these adverse events was <1% in EPESUS (Eplerenone Post-Acute Myocardial Infarction Heart Failure Efficacy and Survival Study) and EMPHASIS-HF without any difference in adverse events between the eplerenone and placebo.428,446

7.3.2.5.3. Aldosterone Receptor Antagonists: Risks of Treatment. The major risk associated with use of aldosterone receptor antagonists is hyperkalemia due to inhibition of potassium excretion, ranging from 2% to 5% in large clinical trials.425-428,446 to 24% to 36% in population-based registries.479,480 Routine triple combination of an ACE inhibitor, ARB, and aldosterone receptor antagonist should be avoided.

The development of potassium levels >5.5 mEq/L (approximately 12% in EMPHASIS-HF426) should generally trigger discontinuation or dose reduction of the aldosterone receptor antagonist unless other causes are identified. The development of worsening renal function should lead to careful evaluation of the entire medical regimen and consideration for stopping the aldosterone receptor antagonist. Patients should be instructed specifically to stop the aldosterone receptor antagonist during an episode of diarrhea or dehydration or while loop diuretic therapy is interrupted.

7.3.2.6. Hydralazine and Isosorbide Dinitrate: Recommendations

Class I

1. The combination of hydralazine and isosorbide dinitrate is recommended to reduce morbidity and mortality for patients self-described as African Americans with NYHA class III–IV HFrEF receiving optimal therapy with ACE inhibitors and beta blockers, unless contraindicated.23,424 (Level of Evidence: A)

Class IIa

1. A combination of hydralazine and isosorbide dinitrate can be useful to reduce morbidity or mortality in patients with current or prior symptomatic HFrEF who cannot be given an ACE inhibitor or ARB because of drug intolerance, hypotension, or renal insufficiency, unless contraindicated.49 (Level of Evidence: B)

In a large-scale trial that compared the vasodilator combination with placebo, the use of hydralazine and isosorbide dinitrate reduced mortality but not hospitalizations in patients with HF treated with digoxin and diuretics but not an ACE inhibitor or beta blocker.449 However, in 2 other trials that compared the vasodilator combination with an ACE inhibitor, the ACE inhibitor produced more favorable effects on survival.412,482 A post hoc retrospective analysis of these vasodilator trials demonstrated particular efficacy of isosorbide dinitrate and hydralazine in the African American cohort.423 In a subsequent trial, which was limited to patients self-described as African American, the addition of a fixed-dose combination of hydralazine and isosorbide dinitrate to standard therapy with an ACE inhibitor or ARB, a beta blocker, and an aldosterone antagonist offered significant benefit.424

7.3.2.6.1. Hydralazine and Isosorbide Dinitrate: Selection of Patients. The combination of hydralazine and isosorbide dinitrate is recommended for African Americans with HFrEF who remain symptomatic despite concomitant use of ACE inhibitors, beta blockers, and aldosterone antagonists. Whether this benefit is evident in non–African Americans with HFrEF remains to be investigated. The combination of hydralazine and isosorbide dinitrate should not be used for the treatment of HFrEF in patients who have no prior use of standard neurohumoral antagonist therapy and should not be substituted for ACE inhibitor or ARB therapy in patients who are tolerating therapy without difficulty. Despite the lack of data with the vasodilator combination in patients who are intolerant of ACE inhibitors or ARBs, the combined use of hydralazine and isosorbide dinitrate may be considered as a therapeutic option in such patients.

7.3.2.6.2. Hydralazine and Isosorbide Dinitrate: Initiation and Maintenance. If the fixed-dose combination is available, the initial dose should be 1 tablet containing 37.5 mg of hydralazine hydrochloride and 20 mg of isosorbide dinitrate 3 times daily. The dose can be increased to 2 tablets 3 times daily for a total daily dose of 225 mg of hydralazine hydrochloride and 120 mg of isosorbide dinitrate. When the 2 drugs are used separately, both pills should be administered at least 3 times daily. Initial low doses of the drugs given separately may be progressively increased to a goal similar to that achieved in the fixed-dose combination trial.424

7.3.2.6.3. Hydralazine and Isosorbide Dinitrate: Risks of Treatment. Adherence to this combination has generally been poor because of the large number of tablets required, frequency of administration, and the high incidence of adverse reactions.412,449 Frequent adverse effects include headache, dizziness, and gastrointestinal complaints. Nevertheless, the benefit of these drugs can be substantial and warrant a slower titration of the drugs to enhance tolerance of the therapy.

See Table 18 for a summary of the treatment benefit of GDMT in HFrEF.

7.3.2.7. Digoxin: Recommendation

Class IIa

1. Digoxin can be beneficial in patients with HFpEF, unless contraindicated, to decrease hospitalizations for HF.488–491 (Level of Evidence: B)

Several placebo-controlled trials have shown that treatment with digoxin for 1 to 3 months can improve symptoms, HRQOL, and exercise tolerance in patients with mild to moderate HF.488–491 These benefits have been seen regardless of the underlying rhythm (normal sinus rhythm or AF), cause of HF (ischemic or nonischemic cardiomyopathy), or concomitant therapy (with or without ACE inhibitors). In a long-term trial that primarily enrolled patients with NYHA class II or III HF, treatment with digoxin for 2 to 5 years had no effect on mortality but modestly reduced the combined risk of death and hospitalization.484

7.3.2.7.1. Digoxin: Selection of Patients. Clinicians may consider adding digoxin in patients with persistent symptoms of HFpEF during GDMT. Digoxin may also be added to the initial regimen in patients with severe symptoms who have not yet responded symptomatically during GDMT.

Alternatively, treatment with digoxin may be delayed until the patient’s response to GDMT has been defined and may be used only in patients who remain symptomatic despite therapy with the neurohormonal antagonists. If a patient is taking digoxin but not an ACE inhibitor or a beta blocker, treatment with digoxin should not be withdrawn, but appropriate therapy with the neurohormonal antagonists should be instituted. Digoxin is prescribed occasionally in patients with HF and AF, but beta blockers are usually more effective when added to digoxin in controlling the ventricular response, particularly during exercise.492–495

Patients should not be given digoxin if they have significant sinus or atrioventricular block unless the block has been addressed with a permanent pacemaker. The drug should be used cautiously in patients taking other drugs that can depress sinus or atrioventricular nodal function or affect digoxin levels (eg, amiodarone or a beta blocker), even though such patients usually tolerate digoxin without difficulty.

7.3.2.7.2. Digoxin: Initiation and Maintenance. Therapy with digoxin is commonly initiated and maintained at a dose of 0.125 to 0.25 mg daily. Low doses (0.125 mg daily or every other day) should be used initially if the patient is >70 years of age, has impaired renal function, or has a low lean body mass.496 Higher doses (eg, digoxin 0.375 to 0.50 mg daily) are rarely used or needed in the management of patients with HF. There is no reason to use loading doses of digoxin to initiate therapy in patients with HF.

Doses of digoxin that achieve a plasma concentration of drug in the range of 0.5 to 0.9 ng/mL are suggested, given the limited evidence currently available. There has been no prospective, randomized evaluation of the relative efficacy or safety of different plasma concentrations of digoxin. Retrospective analysis of 2 studies of digoxin withdrawal found that prevention of worsening HF by digoxin at lower concentrations in plasma (0.5 to 0.9 ng/mL) was as great as that achieved at higher concentrations.497,498

7.3.2.7.3. Digoxin: Risks of Treatment. When administered with attention to dose and factors that alter its metabolism, digoxin is well tolerated by most patients with HF.499 The principal adverse reactions occur primarily when digoxin is administered in large doses, especially in the elderly, but large doses are not necessary for clinical benefits.500–502 The major adverse effects include cardiac arrhythmias (eg, ectopic and re-entrant cardiac rhythms and heart block), gastrointestinal symptoms (eg, anorexia, nausea, and vomiting), and neurological complaints (eg, visual disturbances, disorientation, and confusion). Overt digoxin toxicity is commonly associated with serum digoxin levels >2 ng/mL.

However, toxicity may also occur with lower digoxin levels, especially if hypokalemia, hypomagnesemia, or hypothyroidism coexists.503,504 The concomitant use of clarithromycin, dronedarone, erythromycin, amiodarone, itraconazole, cyclosporine, propafenone, verapamil, or quinidine can increase serum digoxin concentrations and may increase the likelihood of digoxin toxicity.505–507 The dose of digoxin should be reduced if treatment with these drugs is initiated. In addition, a low lean body mass and impaired renal function can also elevate serum digoxin levels, which may explain the increased risk of digoxin toxicity in elderly patients.

7.3.2.8. Other Drug Treatment

7.3.2.8.1. Anticoagulation: Recommendations

Class I

1. Patients with chronic HF with permanent/persistent/paroxysmal AF and an additional risk factor for cardioembolic stroke (history of hypertension, diabetes mellitus, previous stroke or transient ischemic attack, or ≥75 years of age) should receive chronic anticoagulant therapy.508–514 (Level of Evidence: A)

2. The selection of an anticoagulant agent (warfarin, dabigatran, apixaban, or rivaroxaban) for permanent/persistent/paroxysmal AF should be individualized on the basis of risk factors, cost, tolerability, patient preference, potential for drug interactions, and other clinical characteristics, including time in the international normalized ratio therapeutic range if the patient has been taking warfarin. (Level of Evidence: C)

Class IIa

1. Chronic anticoagulation is reasonable for patients with chronic HF who have permanent/persistent/paroxysmal AF but are without an additional risk factor for cardioembolic stroke.515–519 (Level of Evidence: B)

Class III: No Benefit

1. Anticoagulation is not recommended in patients with chronic HFpEF without AF, a prior thromboembolic event, or a cardioembolic source.518–520 (Level of Evidence: B)

*In the absence of contraindications to anticoagulation.
Patients with chronic HF/EF are at an increased risk of thromboembolic events due to stasis of blood in dilated hypokinetic cardiac chambers and in peripheral blood vessels, and perhaps due to increased activity of procoagulant factors. However, in large-scale studies, the risk of thromboembolism in clinically stable patients has been low (1% to 3% per year), even in those with a very depressed EF and echocardiographic evidence of intracardiac thrombi. These rates are sufficiently low to limit the detectable benefit of anticoagulation in these patients.

In several retrospective analyses, the risk of thromboembolic events was not lower in patients with HF taking warfarin than in patients not treated with antiarrhythmic drugs. An RCT that compared the outcome of patients with HF/EF assigned to aspirin, warfarin, or clopidogrel was completed, but no therapy appeared to be superior. Another trial compared aspirin with warfarin in patients with reduced LVEF, sinus rhythm, and no cardioembolic source and demonstrated no difference in either the primary outcome of death, stroke, or intracerebral hemorrhage. There was also no difference in the combined outcome of death, ischemic stroke, intracerebral hemorrhage, MI, or HF hospitalization. There was a significant increase in major bleeding with warfarin. Given that there is no overall benefit of warfarin and an increased risk of bleeding, there is no compelling evidence to use warfarin or aspirin in patients with HF/EF in the absence of a specific indication.

The efficacy of long-term warfarin for the prevention of stroke in patients with AF is well established. However, the ACCF/AHA guidelines for AF recommend use of the CHADS2 (Congestive heart failure, Hypertension, Age ≥75 years, Diabetes mellitus, previous Stroke/transient ischemic attack [doubled risk weight]) score to assess patient risk for adverse outcomes before initiating anticoagulation therapy. More recently, a revised score, CHADS2-VASc, has been suggested as more applicable to a wider range of patients, but this revised score has not yet been fully studied in patients with HF. Regardless of whether patients receive rhythm or rate control, anticoagulation is recommended for patients with HF and AF for stroke prevention in the presence of at least 1 additional risk factor. For patients with HF and AF in the absence of another cardioembolic risk factor, anticoagulation is reasonable.

Trials of newer oral anticoagulants have compared efficacy and safety with warfarin therapy rather than placebo. Several new oral anticoagulants are now available, including the factor Xa inhibitors apixaban and rivaroxaban and the direct thrombin inhibitor dabigatran. These drugs have few food and drug interactions compared with warfarin and no need for routine coagulation monitoring or dose adjustment. The fixed dosing together with fewer interactions may simplify patient management, particularly with the polypharmacy commonly seen in HF. These drugs have a potential for an improved benefit–risk profile compared with warfarin, which may increase their use in practice, especially in those at increased bleeding risk. However, important adverse effects have been noted with these new anticoagulants, including gastrointestinal distress, which may limit compliance. At present, there is no commercially available agent to reverse the effect of these newer drugs. Trials comparing new anticoagulants with warfarin have enrolled >10000 patients with HF. As more detailed evaluations of the comparative benefits and risks of these newer agents in patients with HF are still pending, the writing committee considered their use in patients with HF and nonvalvular AF as an alternative to warfarin to be reasonable.

The benefit afforded by low-dose aspirin in patients with systolic HF but no previous MI or known CAD (or specifically in patients proven free of CAD) remains unknown. A Cochrane review failed to find sufficient evidence to support its use. Retrospective and observational studies again had conflicting results and used very different criteria to identify patients as nonischemic, with some demonstrating protection from aspirin overall or only in patients with more severe depression of systolic function, whereas others found no benefit from aspirin. The high incidence of diabetes mellitus and hypertension in most HF studies, combined with a failure to use objective methods to exclude CAD in enrolled patients, may leave this question unanswered. Currently, data are insufficient to recommend aspirin for empiric primary prevention in HF patients known to be free of atherosclerotic disease and without additional risk factors.

See Online Data Supplement 21 for additional data on anticoagulants.

7.3.2.8.2. Statins: Recommendation
Class III: No Benefit

1. Statins are not beneficial as adjunctive therapy when prescribed solely for the diagnosis of HF in the absence of other indications for their use. (Level of Evidence: A)

Statin therapy has been broadly implicated in prevention of adverse cardiovascular events, including new-onset HF. Originally designed to lower cholesterol in patients with cardiovascular disease, statins are increasingly recognized for their favorable effects on inflammation, oxidative stress, and vascular performance. Several observational and post hoc analyses from large clinical trials have implied that statin therapy may provide clinical benefit to patients with HF. However, 2 large RCTs have demonstrated that rosuvastatin has neutral effects on long-term outcomes in patients with chronic HF/EF when added to standard GDMT. At present, statin therapy should not be prescribed primarily for the treatment of HF to improve clinical outcomes.

See Online Data Supplement 22 for additional data on statin therapy.

7.3.2.8.3. Omega-3 Fatty Acids: Recommendation
Class IIa

1. Omega-3 polyunsaturated fatty acid (PUFA) supplementation is reasonable to use as adjunctive therapy in patients with NYHA class II–IV symptoms and HF/EF or HFpEF, unless contraindicated, to reduce mortality and cardiovascular hospitalizations. (Level of Evidence: B)

Supplementation with omega-3 PUFAs has been evaluated as an adjunctive therapy for cardiovascular disease and HF. Trials in primary and secondary prevention of coronary heart disease...
showed that omega-3 PUFA supplementation results in a 10% to 20% risk reduction in fatal and nonfatal cardiovascular events. The GISSI (Gruppo Italiano per lo Studio della Sopravvivenza nell’Infarto miocardico) Prevenzione trial demonstrated a 21% reduction in death among post-MI patients taking 1 g of omega-3 PUFA (850 mg to 882 mg of eicosapentaenoic acid [EPA] and docosahexaenoic acid [DHA] as ethyl esters in the ratio of 1:1.2). Post hoc subgroup analysis revealed that this reduction in mortality and SCD was concentrated in the approximately 2000 patients with reduced LVEF. The GISSI-HF investigators randomized 6975 patients in NYHA class II–IV chronic HF to 1 g daily of omega-3 PUFA (850 mg to 882 mg EPA/DHA) or matching placebo. Death from any cause was reduced from 29% with placebo to 27% in those treated with omega-3 PUFA. The outcome of death or admission to hospital for a cardiovascular event was also significantly reduced. In reported studies, this therapy has been safe and very well tolerated. Further investigations are needed to better define optimal dosing and formulation of omega-3 PUFA supplements. The use of omega-3 PUFA supplementation is reasonable as adjunctive therapy in patients with chronic HF.

See Online Data Supplement 23 for additional data on omega-3 fatty acids.

7.3.2.9. Drugs of Unproven Value or That May Worsen HF: Recommendations

Class III: No Benefit

1. Nutritional supplements as treatment for HF are not recommended in patients with current or prior symptoms of HFrEF. (Level of Evidence: B)

2. Hormonal therapies other than to correct deficiencies are not recommended for patients with current or prior symptoms of HFrEF. (Level of Evidence: C)

Class III: Harm

1. Drugs known to adversely affect the clinical status of patients with current or prior symptoms of HFrEF are potentially harmful and should be avoided or withdrawn whenever possible (eg, most antiarrhythmic drugs, most calcium channel–blocking drugs [except amlodipine], NSAIDs, or thiazolidinediones). (Level of Evidence: B)

2. Long-term use of infused positive inotropic drugs is potentially harmful for patients with HFrEF, except as palliation for patients with end-stage disease who cannot be stabilized with standard medical treatment (see recommendations for stage D). (Level of Evidence: C)

7.3.2.9.1. Nutritional Supplements and Hormonal Therapies.

Patients with HF, particularly those treated with diuretics, may become deficient in vitamins and micronutrients. Several nutritional supplements (eg, coenzyme Q10, carnitine, taurine, and antioxidants) and hormonal therapies (eg, growth hormone or thyroid hormone) have been proposed for the treatment of HF. Testosterone has also been evaluated for its beneficial effect in HF with modest albeit preliminary effects. Aside from replenishment of documented deficiencies, published data have failed to demonstrate benefit for routine vitamin, nutritional, or hormonal supplementation.

In most data or other literature regarding nutraceuticals, there are issues, including outcomes analyses, adverse effects, and drug-nutraceutical interactions, that remain unresolved.

No clinical trials have demonstrated improved survival rates with use of nutritional or hormonal therapy, with the exception of omega-3 fatty acid supplementation as previously noted. Some studies have suggested a possible effect for coenzyme Q10 in reduced hospitalization rates, dyspnea, and edema in patients with HF, but these benefits have not been seen uniformly. Because of possible adverse effects and drug interactions of nutritional supplements and their widespread use, clinicians caring for patients with HF should routinely inquire about their use. Until more data are available, nutritional supplements or hormonal therapies are not recommended for the treatment of HF.

7.3.2.9.2. Antiarrhythmic Agents. With atrial and ventricular arrhythmias contributing to the morbidity and mortality of HF, various classes of antiarrhythmic agents have been repeatedly studied in large RCTs. Instead of conferring survival benefit, however, nearly all antiarrhythmic agents increase mortality in the HF population. Most antiarrhythmics have some negative inotropic effect and some, particularly the class I and class III antiarrhythmic drugs, have proarrhythmic effects. Hence, class I sodium channel antagonists and the class III potassium channel blockers d-sotalol and dronedarone should be avoided in patients with HF. Amiodarone and dofetilide are the only antiarrhythmic agents to have neutral effects on mortality in clinical trials of patients with HF and thus are the preferred drugs for treating arrhythmias in this patient group.

See Online Data Supplement 24 for additional data on antiarrhythmic agents.

7.3.2.9.3. Calcium Channel Blockers: Recommendation

Class III: No Benefit

1. Calcium channel–blocking drugs are not recommended as routine treatment for patients with HFrEF. (Level of Evidence: A)

By reducing peripheral vasoconstriction and LV afterload, calcium channel blockers were thought to have a potential role in the management of chronic HF. However, first-generation dihydropyridine and nondihydropyridine calcium channel blockers also have myocardial depressant activity. Several clinical trials have demonstrated either no clinical benefit or even worse outcomes in patients with HF treated with these drugs. Despite their greater selectivity for calcium channels in vascular smooth muscle cells, second-generation calcium channel blockers, dihydropyridine derivatives such as amlodipine and felodipine, have failed to demonstrate any functional or survival benefit in patients with HF. Amlodipine, however, may be considered in the management of hypertension or ischemic heart disease in patients with HF because it is generally well tolerated and has neutral effects on morbidity and mortality in large RCTs. In general, calcium channel blockers should be avoided in patients with HFrEF.

See Online Data Supplement 25 for additional data on calcium channel blockers.
7.3.2.9.4. Nonsteroidal Anti-Inflammatory Drugs. NSAIDs inhibit the synthesis of renal prostaglandins, which mediate vasodilation in the kidneys and directly inhibit sodium resorption in the thick ascending loop of Henle and collecting tubule. Hence, NSAIDs can cause sodium and water retention and blunt the effects of diuretics. Several observational cohort studies have revealed increased morbidity and mortality in patients with HF using either nonselective or selective NSAIDs.554–556,580–582
See Online Data Supplement 26 for additional data on NSAIDs.

7.3.2.9.5. Thiazolidinediones. Thiazolidinediones increase insulin sensitivity by activating nuclear peroxisome proliferator-activated receptor gamma. Expressed in virtually all tissues, peroxisome proliferator-activated receptor gamma also regulates sodium reabsorption in the collecting ducts of the kidney. In clinical trials, thiazolidinediones have been associated with increased incidence of HF events, even in those without any prior history of clinical HF.557,583–588
See Table 19 for a summary of recommendations from this section and Table 20 for strategies for achieving optimal GDMT; see Online Data Supplement 27 for additional data on thiazolidinediones.

7.3.3. Pharmacological Treatment for Stage C HFpEF: Recommendations
See Table 21 for a summary of recommendations from this section.

Class I
1. Systolic and diastolic blood pressure should be controlled in patients with HFpEF in accordance with published clinical practice guidelines to prevent morbidity.(Level of Evidence: B)
2. Diuretics should be used for relief of symptoms due to volume overload in patients with HFpEF. (Level of Evidence: C)

Class IIa
1. Coronary revascularization is reasonable in patients with CAD in whom symptoms (angina) or demonstrable myocardial ischemia is judged to be having an adverse effect on symptomatic HFpEF despite GDMT. (Level of Evidence: C)
2. Management of AF according to published clinical practice guidelines in patients with HFpEF is reasonable to improve symptomatic HF (Section 9.1). (Level of Evidence: C)
3. The use of beta-blocking agents, ACE inhibitors, and ARBs in patients with hypertension is reasonable to control blood pressure in patients with HFpEF. (Level of Evidence: C)

Class IIb
1. The use of ARBs might be considered to decrease hospitalizations for patients with HFpEF. (Level of Evidence: B)

Class III: No Benefit
1. Routine use of nutritional supplements is not recommended for patients with HFpEF. (Level of Evidence: C)

Trials using comparable and efficacious agents for HFrEF have generally been disappointing when used in patients with HFpEF.590 Thus, most of the recommended therapies for HFpEF are directed at symptoms, especially comorbidities, and risk factors that may worsen cardiovascular disease.

Blood pressure control concordant with existing hypertension guidelines remains the most important recommendation in patients with HFpEF. Evidence from an RCT has shown that improved blood pressure control reduces hospitalization for HF,591 decreases cardiovascular events, and reduces HF mortality in patients without prevalent HF.511 In hypertensive patients with HFpEF, aggressive treatment (often with several drugs with complementary mechanisms of action) is recommended. ACE inhibitors and/or ARBs are often considered as first-line agents. Specific blood pressure targets in HFpEF have not been firmly established; thus, the recommended targets are those used for general hypertensive populations.

CAD is common in patients with HFpEF592; however, there are no studies to determine the impact of revascularization on symptoms or outcomes specifically in patients with HFpEF. In general, contemporary revascularization guidelines10,12 should be used in the care of patients with HFpEF and concomitant CAD. Specific to this population, it might be reasonable to consider revascularization in patients for whom ischemia appears to contribute to HF symptoms, although this determination can be difficult.

Theoretical mechanisms for the worsening of HF symptoms by AF among patients with HFpEF include shortened diastolic filling time with tachycardia and the loss of atrial contribution to LV diastolic filling. Conversely, chronotropic incompetence is also a concern. Slowing the heart rate is useful in tachycardia but not in normal resting heart rate; a slow heart rate prolongs diastasis and worsens chronotropic incompetence. Currently, there are no specific trials of rate versus rhythm control in HFpEF.

7.3.4. Device Therapy for Stage C HFrEF: Recommendations
See Table 22 for a summary of recommendations from this section.

Class I
1. ICD therapy is recommended for primary prevention of SCD to reduce total mortality in selected patients with nonischemic DCM or ischemic heart disease at least 40 days post-MI with LVEF of 35% or less and NYHA class II or III symptoms on GDMT, who have reasonable expectation of meaningful survival for more than 1 year.†535,593 (Level of Evidence: A)
2. CRT is indicated for patients who have LVEF of 35% or less, sinus rhythm, left bundle-branch block (LBBB) with a QRS duration of 150 ms or greater, and NYHA class II, III, or ambulatory IV symptoms on GDMT. (Level of Evidence: A for NYHA class III/IV58,78,116,594; Level of Evidence: B for NYHA class II105,596)

†Counseling should be specific to each individual patient and should include documentation of a discussion about the potential for sudden death and nonsudden death from HF or noncardiac conditions. Information should be provided about the efficacy, safety, and potential complications of an ICD and the potential for defibrillation to be inactivated if desired in the future, notably when a patient is approaching end of life. This will facilitate shared decision making between patients, families, and the medical care team about ICDs.30

Table 20. Strategies for Achieving Optimal GDMT

1. Uptitrate in small increments to the recommended target dose or the highest tolerated dose for those medications listed in Table 15 with an appreciation that some patients cannot tolerate the full recommended doses of all medications, particularly patients with low baseline heart rate or blood pressure or with a tendency to postural symptoms.

2. Certain patients (eg, the elderly, patients with chronic kidney disease) may require more frequent visits and laboratory monitoring during dose titration and more gradual dose changes. However, such vulnerable patients may accrue considerable benefits from GDMT. Inability to tolerate optimal doses of GDMT may change after disease-modifying interventions such as CRT.

3. Monitor vital signs closely before and during up titration, including postural changes in blood pressure or heart rate, particularly in patients with orthostatic symptoms, bradycardia, and/or “low” systolic blood pressure (eg, 80 to 100 mmHg).

4. Alternate adjustments of different medication classes (especially ACE inhibitors/ARBs and beta blockers) listed in Table 15. Patients with elevated or normal blood pressure and heart rate may tolerate faster incremental increases in dosages.

5. Monitor renal function and electrolytes for rising creatinine and hyperkalemia, recognizing that an initial rise in creatinine may be expected and does not necessarily require discontinuation of therapy; discuss tolerable levels of creatinine above baseline with a nephrologist if necessary.

6. Patients may complain of symptoms of fatigue and weakness with dose increases; in the absence of instability in vital signs, reassure them that these symptoms are often transient and usually resolve within a few days of these changes in therapy.

7. Discourage sudden spontaneous discontinuation of GDMT medications by the patient and/or other clinicians without discussion with managing clinicians.

8. Carefully review doses of other medications for HF symptom control (eg, diuretics, nitrates) during uptitration.

9. Consider temporary adjustments in dosages of GDMT during acute episodes of noncardiac illnesses (eg, respiratory infections, risk of dehydration, etc).

10. Educate patients, family members, and other clinicians about the expected benefits of achieving GDMT, including an understanding of the potential benefits of myocardial reverse remodeling, increased survival, and improved functional status and HRQOL.

Counseling should be specific to each individual patient and should include documentation of a discussion about the potential for sudden death and non sudden death from HF or noncardiac conditions. Information should be provided about the efficacy, safety, and potential complications of an ICD and the potential for defibrillation to be inactivated if desired in the future, notably when a patient is approaching end of life. This will facilitate shared decision making between patients, families, and the medical care team about ICDs.

This will facilitate shared decision making between patients, families, and the medical care team about ICDs.

Class IIb

1. The usefulness of implantation of an ICD is of uncertain benefit to prolong meaningful survival in patients with a high risk of nonsudden death as predicted by frequent hospitalizations, advanced frailty, or comorbidities such as systemic malignancy or severe renal dysfunction.†‡ (Level of Evidence: B)

2. CRT may be considered for patients who have LVEF of 35% or less, sinus rhythm, a non-LBBB pattern with QRS duration of 120 to 149 ms, and NYHA class III/ambulatory class IV on GDMT.‡ (Level of Evidence: B)

Class III: No Benefit

1. CRT is not recommended for patients with NYHA class I or II symptoms and non-LBBB pattern with QRS duration less than 150 ms.‡ (Level of Evidence: B)

2. CRT is not indicated for patients whose comorbidities and/or frailty limit survival with good functional capacity to less than 1 year. (Level of Evidence: C)

See Figure 2, indications for CRT therapy algorithm.
7.3.4.1. Implantable Cardioverter-Defibrillator

Patients with reduced LVEF are at increased risk for ventricular tachyarrhythmias leading to SCD. Sudden death in HF/EF has been substantially decreased by neurohormonal antagonists that alter disease progression and also protect against arrhythmias. Nonetheless, patients with systolic dysfunction remain at increased risk for SCD due to ventricular tachyarrhythmias. Patients who have had sustained ventricular tachycardia, ventricular fibrillation, unexplained syncope, or cardiac arrest are at highest risk for recurrence. Indications for ICD therapy as secondary prevention of SCD in these patients are also discussed in the ACCF/AHA/HRS device-based therapy guideline.4

The use of ICDs for primary prevention in patients with HF/EF should be considered only in the setting of optimal GDMT and with a minimum of 3 to 6 months of appropriate medical therapy. A repeat assessment of ventricular function is appropriate to assess recovery of ventricular function on GDMT that would be above the threshold where an ICD is indicated. This therapy will often improve ventricular function to a range for which the risk of sudden death is too low to warrant placement of an ICD. In addition, the trials of ICDs for primary prevention of SCD studied patients who were already on GDMT.

ICDs are highly effective in preventing death from ventricular arrhythmias, but frequent shocks can decrease HRQOL and lead to posttraumatic stress syndrome.6,15 Therapy with antiarrhythmic drugs and catheter ablation for ventricular tachycardia can decrease the number of ICD shocks given and can sometimes improve ventricular function in cases of very frequent ventricular tachyarrhythmias. Refined device programming can optimize pacing therapies to avert the need for shocks, minimize inappropriate shocks, and avoid aggravation of HF by frequent ventricular pacing. Although there have been occasional recalls of device generators, these are exceedingly rare in comparison to complications related to intracardiac device leads, such as fracture and infection.

---

**Figure 2.** Indications for CRT therapy algorithm. CRT indicates cardiac resynchronization therapy; CRT-D, cardiac resynchronization therapy-defibrillator; GDMT, guideline-directed medical therapy; HF, heart failure; ICD, implantable cardioverter-defibrillator; LBBB, left bundle-branch block; LVEF, left ventricular ejection fraction; MI, myocardial infarction; and NYHA, New York Heart Association.

**Table 1.** Colors correspond to the class of recommendations in the ACCF/AHA Table 1.

Benefit for NYHA class I and II patients has only been shown in CRT-D trials, and while patients may not experience immediate symptomatic benefit, late remodeling may be avoided along with long-term HF consequences. There are no trials that support CRT-pacing (without ICD) in NYHA class I and II patients. Thus, it is anticipated these patients would receive CRT-D unless clinical reasons or personal wishes make CRT-pacing more appropriate. In patients who are NYHA class III and ambulatory class IV, CRT-D may be chosen but clinical reasons and personal wishes may make CRT-pacing appropriate to improve symptoms and quality of life when an ICD is not expected to produce meaningful benefit in survival.
ICDs are indicated only in patients with a reasonable expectation of survival with good functional status beyond a year, but the range of uncertainty remains wide. The complex decision about the relative risks and benefits of ICDs for primary prevention of SCD must be individualized for each patient. Unlike other therapies that can prolong life with HF, the ICD does not modify the disease except in conjunction with CRT. Patients with multiple comorbidities have a higher rate of implant complications and higher competing risks of death from noncardiac causes.618 Older patients, who are at a higher risk of nonsudden death, are often underrepresented in the pivotal trials where the average patient is <65 years of age.617 The major trials for secondary prevention of SCD showed no benefit in patients >75 years of age,618 and a meta-analysis of primary prevention of SCD also suggested lesser effectiveness of ICDs.619 Populations of patients with multiple HF hospitalizations, particularly in the setting of chronic kidney disease, have a median survival rate of <2 years, during which the benefit of the ICD may not be realized.620 There is widespread recognition of the need for further research to identify patients most and least likely to benefit from ICDs for primary prevention of SCD in HF. Similar considerations apply to the decision to replace the device generator.

Consideration of ICD implantation is highly appropriate for shared decision making.30 The risks and benefits carry different relative values depending on patient goals and preferences. Discussion should include the potential for SCD and nonsudden death from HF or noncardiac conditions. Information should be provided in a format that patients can understand about the estimated efficacy, safety, and potential complications of an ICD and the ease with which defibrillation can be inactivated if no longer desired.620 As the prevalence of implantable devices increases, it is essential that clearly defined processes be in place to support patients and families when decisions about deactivation arise.621

7.3.4.2. Cardiac Resynchronization Therapy

In approximately one third of patients, HF progression is accompanied by substantial prolongation of the QRS interval, which is associated with worse outcome.622 Multisite ventricular pacing (termed CRT or biventricular pacing) can improve ventricular contractile function, diminish secondary mitral regurgitation, reverse ventricular remodeling, and sustain improvement in LVEF. Increased blood pressure with CRT can allow increased titration of neurohormonal antagonist medications that may further contribute to improvement. Benefits were proven initially in trials of patients with NYHA class III or ambulatory class IV HF symptoms and QRS duration ≥120 to 130 ms. These results have included a decrease of approximately 30% in rehospitalization and reductions in all-cause mortality in the range of 24% to 36%. Improvement in survival is evident as early as the first 3 months of therapy. Functional improvements have been demonstrated on average as a 1 to 2 mL/kg/min increase in peak oxygen consumption, 50- to 70-meter increase in 6-minute walk distance, and a reduction of 10 points or more in the 0- to 105-point scale of the Minnesota Living With Heart Failure Questionnaire, all considered clinically significant. These results include patients with a wide range of QRS duration and, in most cases, sinus rhythm.78,116,594,623

Although it is still not possible to predict with confidence which patients will improve with CRT, further experiences have provided some clarification. Benefit appears confined largely to patients with a QRS duration of at least 150 ms and LBBB pattern.624-628 The weight of the evidence has been accumulated from patients with sinus rhythm, with meta-analyses indicating substantially less clinical benefit in patients with permanent AF.604,605 Because effective CRT requires a high rate of ventricular pacing,606 the benefit for patients with AF is most evident in patients who have undergone atrioventricular nodal ablation, which ensures obligate ventricular pacing.501-603

In general, most data derive from patients with class III symptoms. Patients labeled as having class IV symptoms account for a small minority of patients enrolled. Furthermore, these patients, characterized as “ambulatory” NYHA class IV, are not refractory due to fluid retention, frequently hospitalized for HF, or dependent on continuous intravenous inotropic therapy. CRT should not be considered as “rescue” therapy for stage D HF. In addition, patients with significant noncardiac limitations are unlikely to derive major benefit from CRT.

Since publication of the 2009 HF guideline,38 new evidence supports extension of CRT to patients with milder symptoms. LV remodeling was consistently reversed or halted, with benefit also in reduction of HF hospitalizations.595,596,599 In this population with low 1-year mortality, reduction of HF hospitalization dominated the composite primary endpoints, but a mortality benefit was subsequently observed in a 2-year extended follow-up study630 and in a meta-analysis of 5 trials of CRT in mild HF that included 4213 patients with class II symptoms.531 Overall benefits in class II HF were noted only in patients with QRS ≥150 ms and LBBB, with an adverse impact with shorter QRS duration or non-LBBB.

The entry criterion for LVEF in CRT trials has ranged from ≤30% to ≤40%. The trials with class III–IV symptoms included patients with LVEF ≤35%,78,116,594 The 2 individual trials showing improvement in mortality with class II HF included patients with LVEF ≤30%.632,633 Trials demonstrating significant improvement in LV size and EF have included patients with LVEF ≤35%.115 and LVEF ≤40%,99 which also showed reduction in the secondary endpoint of time to hospitalization and a reduction in the composite of clinical HF events comparable to that of all of the CRT trials.824 The congruence of evidence from the totality of CRT trials with regard to remodeling and HF events supports a common threshold of 35% for benefit from CRT in patients with class II, III, and IV HF symptoms. For patients with class II HF, all but 1 of the trials tested CRT in combination with an ICD, whereas there is evidence for benefit with both CRT-defibrillator and CRT alone in patients with class III–IV symptoms.78,116

Although the weight of evidence is substantial for patients with class II symptoms, these CRT trials have included only 372 patients with class I symptoms, most with concomitant ICD for the postinfarction indication.98,99 Considering the risk–benefit ratio for class I, more concern is raised by the early adverse events, which in 1 trial occurred in 13% of patients with CRT-ICD compared with 6.7% in patients with ICD only.98 On the basis of limited data from MADIT-CRT (Multicenter Automatic Defibrillator Implantation Trial-Cardiac Resynchronization Therapy), CRT-ICD may be...
considered for patients with class I symptoms ≥40 days after MI, LVEF ≤30%, sinus rhythm, LBBB, and QRS ≥150 ms.595

These indications for CRT all include expectation for ongoing GDMT and diuretic therapy as needed for fluid retention. In addition, regular monitoring is required after device implantation because adjustment of HF therapies and reprogramming of device intervals may be required. The trials establishing the benefit of these interventions were conducted in centers offering expertise in both implantation and follow-up. Recommendations for CRT are made with the expectation that they will be performed in centers with expertise and outcome comparable to that of the trials that provide the bases of evidence. The benefit–risk ratio for this intervention would be anticipated to be diminished for patients who do not have access to these specialized care settings or who are nonadherent.

See Online Data Supplements 28 and 29 for additional data on device therapy and CRT.

7.4. Stage D

7.4.1. Definition of Advanced HF

A subset of patients with chronic HF will continue to progress and develop persistently severe symptoms despite maximum GDMT. Various terminologies have been used to describe this group of patients who are classified with ACCF/AHA stage D HF, including “advanced HF,” “end-stage HF,” and “refractory HF.” In the 2009 ACCF/AHA HF guideline, stage D was defined as "patients with truly refractory HF who might be eligible for specialized, advanced treatment strategies, such as MCS, procedures to facilitate fluid removal, continuous inotropic infusions, or cardiac transplantation or other innovative or experimental surgical procedures, or for end-of-life care, such as hospice."38 The European Society of Cardiology has developed a definition of advanced HF with objective criteria that can be useful (Table 23).

7.4.2. Important Considerations in Determining If the Patient Is Refractory

Patients considered to have stage D HF should be thoroughly evaluated to ascertain that the diagnosis is correct and that there are no remediable etiologies or alternative explanations for advanced symptoms. For example, it is important to determine that HF and not a concomitant pulmonary disorder is the basis of dyspnea. Similarly, in those with presumed cardiac cachexia, other causes of weight loss should be ruled out. Likewise, other reversible factors such as thyroid disorders should be treated. Severely symptomatic patients presenting with a new diagnosis of HF can often improve substantially if they are initially stabilized. Patients should also be evaluated for nonadherence to medications, sodium restriction, and/or daily weight monitoring.641 Finally, a careful review of prior medical management should be conducted to verify that all evidence-based therapies likely to improve clinical status have been considered.

See Online Data Supplements 30 and 31 for additional data on therapies—important considerations and sildenafil.

7.4.3. Water Restriction: Recommendation

Class IIa

1. Fluid restriction (1.5 to 2 L/d) is reasonable in stage D, especially in patients with hyponatremia, to reduce congestive symptoms. (Level of Evidence: C)

Recommendations for fluid restriction in HF are largely driven by clinical experience. Sodium and fluid balance recommendations are best implemented in the context of weight and symptom monitoring programs. Routine strict fluid restriction in all

---

**Table 23. ESC Definition of Advanced HF**

1. Severe symptoms of HF with dyspnea and/or fatigue at rest or with minimal exertion (NYHA class III or IV)
2. Episodes of fluid retention (pulmonary and/or systemic congestion, peripheral edema) and/or reduced cardiac output at rest (peripheral hypoperfusion)
3. Objective evidence of severe cardiac dysfunction shown by at least 1 of the following:
   a. LVEF <30%
   b. Pseudonormal or restrictive mitral inflow pattern
   c. Mean PCWP >16 mm Hg and/or RAP >12 mm Hg by PA catheterization
   d. High BNP or NT-proBNP plasma levels in the absence of noncardiac causes
4. Severe impairment of functional capacity shown by 1 of the following:
   a. Inability to exercise
   b. 6-Minute walk distance ≤300 m
   c. Peak VO2 <14 ml/kg/min
5. History of ≥1 HF hospitalization in past 6 mo
6. Presence of all the previous features despite "attempts to optimize" therapy, including diuretics and GDMT, unless these are poorly tolerated or contraindicated, and CRT when indicated

BNP indicates B-type natriuretic peptide; CRT, cardiac resynchronization therapy; ESC, European Society of Cardiology; GDMT, guideline-directed medical therapy; HF, heart failure; LVEF, left ventricular ejection fraction; NT-proBNP, N-terminal pro-B-type natriuretic peptide; NYHA, New York Heart Association; PA, pulmonary artery; PWCP, pulmonary capillary wedge pressure; and RAP, right atrial pressure.

Adapted from Metra et al.32

---

**Table 24. Clinical Events and Findings Useful for Identifying Patients With Advanced HF**

- Repeated (≥2) hospitalizations or ED visits for HF in the past year
- Progressive deterioration in renal function (eg, rise in BUN and creatinine)
- Weight loss without other cause (eg, cardiac cachexia)
- Intolerance to ACE inhibitors due to hypotension and/or worsening renal function
- Intolerance to beta blockers due to worsening HF or hypotension
- Frequent systolic blood pressure <90 mm Hg
- Persistent dyspnea with dressing or bathing requiring rest
- Inability to walk 1 block on the level ground due to dyspnea or fatigue
- Recent need to escalate diuretics to maintain volume status, often reaching daily furosemide equivalent dose >160 mg/d and/or use of supplemental metolazone therapy
- Progressive decline in serum sodium, usually to <133 mEq/L
- Frequent ICD shocks

ACE indicates angiotensin-converting enzyme; BUN, blood urea nitrogen; ED, emergency department; HF, heart failure; and ICD, implantable cardioverter-defibrillator.

Adapted from Russell et al.642

<tr>
<th>Profile</th>
<th>Profile Description</th>
<th>Features</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>Critical cardiogenic shock (&quot;Crash and burn&quot;)</td>
<td>Life-threatening hypotension and rapidly escalating inotropic/pressor support, with critical organ hypoperfusion often confirmed by worsening acidosis and lactate levels.</td>
</tr>
<tr>
<td>2</td>
<td>Progressive decline (&quot;Sliding fast&quot; on inotropes)</td>
<td>&quot;Dependent&quot; on inotropic support but nonetheless shows signs of continuing deterioration in nutrition, renal function, fluid retention, or other major status indicator. Can also apply to a patient with refractory volume overload, perhaps with evidence of impaired perfusion, in whom inotropic infusions cannot be maintained due to tachyarrhythmias, clinical ischemia, or other intolerance.</td>
</tr>
<tr>
<td>3</td>
<td>Stable but inotrope dependent</td>
<td>Clinically stable on mild-moderate doses of intravenous inotropes (or has a temporary circulatory support device) after repeated documentation of failure to wean without symptomatic hypotension, worsening symptoms, or progressive organ dysfunction (usually renal).</td>
</tr>
<tr>
<td>4</td>
<td>Resting symptoms on oral therapy at home</td>
<td>Patient who is at home on oral therapy but frequently has symptoms of congestion at rest or with activities of daily living (dressing or bathing). He or she may have orthopnea, shortness of breath during dressing or bathing, gastrointestinal symptoms (abdominal discomfort, nausea, poor appetite), disabling ascites, or severe lower-extremity edema.</td>
</tr>
<tr>
<td>5</td>
<td>Exertion intolerant (&quot;housebound&quot;)</td>
<td>Patient who is comfortable at rest but unable to engage in any activity, living predominantly within the house or housebound.</td>
</tr>
<tr>
<td>6</td>
<td>Exertion limited (&quot;walking wounded&quot;)</td>
<td>Patient who is comfortable at rest without evidence of fluid overload but who is able to do some mild activity. Communications of daily living are comfortable and minor activities outside the home such as visiting friends or going to a restaurant can be performed, but fatigue results within a few minutes or with any meaningful physical exertion.</td>
</tr>
<tr>
<td>7</td>
<td>Advanced NYHA class III</td>
<td>Patient who is clinically stable with a reasonable level of comfortable activity, despite a history of previous decompensation that is not recent. This patient is usually able to walk more than a block. Any decompensation requiring intravenous diuretics or hospitalization within the previous month should make this person a Patient Profile 6 or lower.</td>
</tr>
</tbody>
</table>

*Modifier options: Profiles 3–6 can be modified with the designation frequent flyer for patients with recurrent decompensations leading to frequent (generally at least 2 in last 3 mo or 3 in last 6 mo) emergency department visits or hospitalizations for intravenous diuretics, ultrafiltration, or brief inotropic therapy. Profile 3 can be modified in this fashion if the patient is usually at home. If a Profile 7 patient meets the definition of frequent flyer, the patient should be moved to Profile 6 or worse. Other modifier options include arrhythmia, which should be used in the presence of recurrent ventricular tachyarrhythmias contributing to the overall clinical course (eg, frequent implantable cardioverter-defibrillator shocks or requirement of external defibrillation, usually more than twice weekly); or temporary circulatory support for hospitalized patients profiles 1–3. 435

INTERMACS indicates Interagency Registry for Mechanically Assisted Circulatory Support; and NYHA, New York Heart Association.

Adapted from Stevenson et al. 463

patients with HF regardless of symptoms or other considerations does not appear to result in significant benefit. 644 Limiting fluid intake to around 2 L/d is usually adequate for most hospitalized patients who are not diuretic resistant or significantly hypotensive. In 1 study, patients on a similar sodium and diuretic regimen showed higher readmission rates with higher fluid intake, suggesting that fluid intake affects HF outcomes. 385 Strict fluid restriction may best be used in patients who are either refractory to diuretics or have hyponatremia. Fluid restriction, especially in conjunction with sodium restriction, enhances volume management with diuretics. Fluid restriction is important to manage hyponatremia, which is relatively common with advanced HF and portends a poor prognosis. 545, 648 Fluid restriction may improve serum sodium concentration; however, it is difficult to achieve and maintain. In hot or low-humidity climates, excessive fluid restriction predisposes patients with advanced HF to the risk of heat stroke. Hyponatremia in HF is primarily due to an inability to excrete free water. Norepinephrine and angiotensin II activation result in decreased sodium delivery to the distal tubule, whereas arginine vasopressin increases water absorption from the distal tubule. In addition, angiotensin II also promotes thirst. Thus, sodium and fluid restriction in advanced patients with HF is important.

7.4.4. Inotropic Support: Recommendations

Class I

1. Until definitive therapy (eg, coronary revascularization, MCS, heart transplantation) or resolution of the acute precipitating problem, patients with cardiogenic shock should receive temporary intravenous inotropic support to maintain systemic perfusion and preserve end-organ performance. (Level of Evidence: C)

Class IIa

1. Continuous intravenous inotropic support is reasonable as “bridge therapy” in patients with stage D HF refractory to GDMT and device therapy who are eligible for and awaiting MCS or cardiac transplantation. 647, 648 (Level of Evidence: B)

Class IIb

1. Short-term, continuous intravenous inotropic support may be reasonable in those hospitalized patients presenting with documented severe systolic dysfunction who present with low blood pressure and significantly depressed cardiac output to maintain systemic perfusion and preserve end-organ performance. 592, 649, 650 (Level of Evidence: B)

2. Long-term, continuous intravenous inotropic support may be considered as palliative therapy for symptom control in select patients with stage D HF despite optimal GDMT and device therapy who are not eligible for either MCS or cardiac transplantation. 452–456 (Level of Evidence: B)

Class III: Harm

1. Long-term use of either continuous or intermittent, intravenous parenteral positive inotropic agents, in the absence of specific indications or for reasons
other than palliative care, is potentially harmful in the patient with HF.416,654-659 (Level of Evidence: B)

2. Use of parenteral inotropic agents in hospitalized patients without documented severe systolic dysfunction, low blood pressure, or impaired perfusion and evidence of significantly depressed cardiac output, with or without congestion, is potentially harmful.592,649,659 (Level of Evidence: B)

Despite improving hemodynamic compromise, positive inotropic agents have not demonstrated improved outcomes in patients with HF in either the hospital or outpatient setting.416,654-658 Regardless of their mechanism of action (eg, inhibition of phosphodiesterase, stimulation of adrenergic or dopaminergic receptors, calcium sensitization), chronic oral inotrope treatment increased mortality, mostly related to arrhythmic events. Parenteral inotropes, however, remain as an option to help the subset of patients with HF who are refractory to other therapies and are suffering consequences from end-organ hypoperfusion. Inotropes should be considered only in such patients with systolic dysfunction who have low cardiac index and evidence of depressed cardiac output, with or without congestion, and the long-term effects of acute decompensated, hemodynamically unstable HF are effective in both the short-term (hours to days) management of acute decompensated HF and chronic HF (months to years) management of stage D chronic HF that is refractory to inotropic support, and the long-term strategies, including 1) bridge to transplantation, 2) bridge to destination therapy, and 3) bridge to recovery. Bridge to transplant and destination therapy have the strongest evidence base with respect to survival, functional capacity, and HRQOL benefits.

MCS has emerged as a viable therapeutic option for patients with advanced stage D HF/EF refractory to optimal GDMT and cardiac device intervention. Since its initial use 50 years ago for postcardiotomy shock,676 the implantable VAD continues to evolve.

Designed to assist the native heart, VADs are differentiated by the implant location (intracorporeal versus extracorporeal), approach (percutaneous versus surgical), flow characteristic (pulsatile versus continuous), pump mechanism (volume displacement, axial, centrifugal), and the ventricle(s) supported (left, right, biventricular). VADs are effective in both the short-term (hours to days) management of acute decompensated, hemodynamically unstable HF/EF that is refractory to inotropic support, and the long-term (months to years) management of stage D chronic HF/EF. Nondurable or temporary, MCS provides an opportunity for decisions about the appropriateness of transition to definitive management such as cardiac surgery or durable, that is, permanent, MCS or, in the case of improvement and recovery, suitability for device removal. Nondurable MCS thereby may be helpful as either a bridge to decision or a bridge to recovery.

More common scenarios for MCS, however, are long-term strategies, including 1) bridge to transplantation, 2) bridge to candidacy, and 3) destination therapy. Bridge to transplant and destination therapy have the strongest evidence base with respect to survival, functional capacity, and HRQOL benefits.

Data from INTERMACS provides valuable information on risk factors and outcomes for patients undergoing MCS.
The greatest risk factors for death among patients undergoing bridge to transplant include acuity and severity of clinical condition and evidence of right ventricular failure.677 MCS may also be used as a bridge to candidacy. Retrospective studies have shown reduction in pulmonary pressures with MCS therapy in patients with HF considered to have “fixed” pulmonary hypertension.661–663 Thus, patients who may be transplant-ineligible due to irreversible severe pulmonary hypertension may become eligible with MCS support over time. Other bridge-to-candidacy indications may include obesity and tobacco use in patients who are otherwise candidates for cardiac transplantation. There is ongoing interest in understanding how MCS facilitates LV reverse remodeling. Current scientific and translational research in the area aims to identify clinical, cellular, molecular, and genomic markers of cardiac recovery in the patient with VAD.678,679

See Online Data Supplements 34 and 35 for additional data on MCS and left VADs.

7.4.6. Cardiac Transplantation: Recommendation

Class I

1. Evaluation for cardiac transplantation is indicated for carefully selected patients with stage D HF despite GDMT, device, and surgical management.680 (Level of Evidence: C)

Cardiac transplantation is considered the gold standard for the treatment of refractory end-stage HF. Since the first successful cardiac transplantation in 1967, advances in immunosuppressive therapy have vastly improved the long-term survival of transplant recipients with a 1-, 3-, and 5-year posttransplant survival rate of 87.8%, 78.5%, and 71.7% in adults, respectively.681 Similarly, cardiac transplantation has been shown to improve functional status and HRQOL.682–688 The greatest survival benefit is seen in those patients who are at highest risk of death from advanced HF.680 Cardiopulmonary exercise testing helps refine candidate selection.690–696 Data suggest acceptable posttransplant outcomes in patients with reversible pulmonary hypertension,697 hypertrophic cardiomyopathy,698 peripartum cardiomyopathy,699 restrictive cardiomyopathy,700,701 and muscular dystrophy.702 Selected patients with stage D HF and poor prognosis should be referred to a cardiac transplantation center for evaluation and transplant consideration. Determination of HF prognosis is addressed in Sections 6.1.2 and 7.4.2. The listing criteria and evaluation and management of patients undergoing cardiac transplantation are described in detail by the International Society for Heart and Lung Transplantation.640

See Table 27 for a summary of recommendations from this section, Figure 3 for the stages of HF development; and Online Data Supplement 36 for additional data on transplantation.

*Although optimal patient selection for MCS remains an active area of investigation, general indications for referral for MCS therapy include patients with LVEF <25% and NYHA class III–IV functional status despite GDMT, including, when indicated, CRT, with either high predicted 1- to 2-year mortality (eg, as suggested by markedly reduced peak oxygen consumption and clinical prognostic scores) or dependence on continuous parenteral inotropic support. Patient selection requires a multidisciplinary team of experienced advanced HF and transplantation cardiologists, cardiothoracic surgeons, nurses and ideally, social workers and palliative care clinicians.

BTT indicates bridge to transplant; COR, Class of Recommendation; CRT, cardiac resynchronization therapy; GDMT, guideline-directed medical therapy; HF, heart failure; HFrEF, heart failure with reduced ejection fraction; LOE, Level of Evidence; LVEF, left ventricular ejection fraction; MCS, mechanical circulatory support; N/A, not applicable; and NYHA, New York Heart Association.
8. The Hospitalized Patient

8.1. Classification of Acute Decompensated HF

Hospitalization for HF is a growing and major public health issue. Presently, HF is the leading cause of hospitalization among patients >65 years of age; the largest percentage of expenditures related to HF are directly attributable to hospital costs. Moreover, in addition to costs, hospitalization for acutely decompensated HF represents a sentinel prognostic event in the course of many patients with HF, with a high risk for recurrent hospitalization (eg, 50% at 6 months) and a 1-year mortality rate of approximately 30%. The AHA has published a scientific statement about this condition. The hospitalization risk for recurrent hospitalization (eg, 50% at 6 months) and a 1-year mortality rate of approximately 30%. The AHA has published a scientific statement about this condition.

There is no widely accepted nomenclature for HF syndromes requiring hospitalization. Patients are described as having “acute HF,” “acute HF syndromes,” or “acute(ly) decompensated HF”; while the third has gained greatest acceptance, it too has limitations, for it does not make the important distinction between those with a de novo presentation of HF from those with worsening of previously chronic stable HF.

Data from HF registries have clarified the profile of patients with HF requiring hospitalization. Characteristically, such patients are elderly or near elderly, equally male or female, and typically have a history of hypertension, as well as other medical comorbidities, including chronic kidney disease, hypotension, hematologic abnormalities, and chronic obstructive pulmonary disease. A relatively equal percentage of patients with acutely decompensated HF have impaired versus preserved ejection fraction; HRQOL, health-related quality of life; HTN, hypertension; ICD, implantable cardioverter-defibrillator; LV, left ventricular; LVH, left ventricular hypertrophy; MCS, mechanical circulatory support; and MI, myocardial infarction. Adapted from Hunt et al.

Figure 3. Stages in the development of HF and recommended therapy by stage. ACEI indicates angiotensin-converting enzyme inhibitor; AF, atrial fibrillation; ARB, angiotensin-receptor blocker; CAD, coronary artery disease; CRT, cardiac resynchronization therapy; DM, diabetes mellitus; EF, ejection fraction; GDMT, guideline-directed medical therapy; HF, heart failure; HFpEF, heart failure with preserved ejection fraction; HF–EF, heart failure with reduced ejection fraction; HRQOL, health-related quality of life; HTN, hypertension; ICD, implantable cardioverter-defibrillator; LV, left ventricular; LVH, left ventricular hypertrophy; MCS, mechanical circulatory support; and MI, myocardial infarction. Adapted from Hunt et al.
the adequacy of their peripheral perfusion ("warm" versus "cold")726 (Figure 4). Chest x-ray is variably sensitive for the presence of interstitial or alveolar edema, even in the presence of elevated filling pressures. Thus, a normal chest x-ray does not exclude acutely decompensated HF.717 The utility of natriuretic peptides in patients with acutely decompensated HF has been described in detail in Section 6.3.1. Both BNP and NT-proBNP are useful for the identification or exclusion of acutely decompensated HF in dyspneic patients,718,719 particularly in the context of uncertain diagnosis.720–722 Other options for diagnostic evaluation of patients with suspected acutely decompensated HF, such as acoustic cardiography,723 bioimpedance vector monitoring,724 or noninvasive cardiac output monitoring725 are not yet validated.

8.2. Precipitating Causes of Decompensated HF: Recommendations

Class I

1. ACS precipitating acute HF decomposition should be promptly identified by ECG and serum biomarkers, including cardiac troponin testing, and treated optimally as appropriate to the overall condition and prognosis of the patient. (Level of Evidence: C)

2. Common precipitating factors for acute HF should be considered during initial evaluation, as recognition of these conditions is critical to guide appropriate therapy. (Level of Evidence: C)

ACS is an important cause of worsening or new-onset HF.726 Although acute ST-segment elevation myocardial infarction can be readily apparent on an ECG, other ACS cases may be more challenging to diagnose. Complicating the clinical scenario is that many patients with acute HF, with or without CAD, have serum troponin levels that are elevated.727

However, many other patients may have low levels of detectable troponins not meeting criteria for an acute ischemic event.278,279 Registry data have suggested that the use of coronary angiography is low for patients hospitalized with decompensated HF, and opportunities to diagnose important CAD may be missed.728 For the patient with newly discovered HF, clinicians should always consider the possibility that CAD is an underlying cause of HF.726

Besides ACS, several other precipitating causes of acute HF decompensation must be carefully assessed to inform appropriate treatment, optimize outcomes, and prevent future acute events in patients with HF.730 See list below.

Common Factors That Precipitate Acute Decompensated HF

- Nonadherence with medication regimen, sodium and/or fluid restriction
- Acute myocardial ischemia
- Uncorrected high blood pressure
- AF and other arrhythmias
- Recent addition of negative inotropic drugs (eg, verapamil, nifedipine, diltiazem, beta blockers)
- Pulmonary embolus
- Initiation of drugs that increase salt retention (eg, steroids, thiazolidinediones, NSAIDs)
- Excessive alcohol or illicit drug use
- Endocrine abnormalities (eg, diabetes mellitus, hyperthyroidism, hypothyroidism)
- Concurrent infections (eg, pneumonia, viral illnesses)
- Additional acute cardiovascular disorders (eg, valve disease endocarditis, myopericarditis, aortic dissection)

Hypertension is an important contributor to acute HF, particularly among blacks, women, and those with HFrEF.731 In the ADHERE registry, almost 50% of patients admitted with HF had blood pressure >140/90 mm Hg.107 Abrupt discontinuation of antihypertensive therapy may precipitate worsening HF. The prevalence of AF in patients with acute HF is >30%.731 Infection increases metabolic demands in general. Pulmonary infections, which are common in patients with HF, may add hypoxia to the increased metabolic demands and are associated with worse outcomes.730 The sepsis syndrome is associated with reversible myocardial depression that is likely mediated by cytokine release.732 Patients with HF are hypercoagulable, and the possibility of pulmonary embolus as an etiology of acute decompensation should be considered. Deterioration of renal function can be both a consequence and contributor to decompensated HF. Restoration of normal thyroid function in those with hyperthyroidism or hypothyroidism may reverse abnormal cardiovascular function.731 In patients treated with amiodarone, thyroid disturbances should be suspected.

Excessive sodium and fluid intake may precipitate acute HF.379,384 Medication nonadherence for financial or other reasons is a major cause of hospital admission.374 Several drugs may precipitate acute HF (eg, calcium channel blockers, antiarrhythmic agents, glucocorticoids, NSAIDs and cyclooxygenase-2 inhibitors, thiazolidinediones, and over-the-counter agents like pseudoephedrine). Finally, excessive alcohol intake and use of illicit drugs, such as cocaine and methamphetamine, also need to be investigated as potential causes of HF decompensation.

See Online Data Supplement 37 for additional data on comorbidities in the hospitalized patient.
8.3. Maintenance of GDMT During Hospitalization: Recommendations

Class I

1. In patients with HF/EF experiencing a symptomatic exacerbation of HF requiring hospitalization during chronic maintenance treatment with GDMT, it is recommended that GDMT be continued in the absence of hemodynamic instability or contraindications.195,735,736 (Level of Evidence: B)

2. Initiation of beta-blocker therapy is recommended after optimization of volume status and successful discontinuation of intravenous diuretics, vasodilators, and inotropic agents. Beta-blocker therapy should be initiated at a low dose and only in stable patients. Caution should be used when initiating beta blockers in patients who have required inotropes during their hospital course.195,735,736 (Level of Evidence: B)

The patient’s maintenance HF medications should be carefully reviewed on admission, and it should be decided whether adjustments should be made as a result of the hospitalization. In the majority of patients with HF/EF who are admitted to the hospital, oral HF therapy should be continued, or even uptitrated, during hospitalization. It has been demonstrated that continuation of ACE inhibitors or ARBs and beta blockers for most patients is well tolerated and results in better outcomes.195,735,736 Withholding of, or reduction in, beta-blocker therapy should be considered only in patients hospitalized after recent initiation or increase in beta-blocker therapy or with marked volume overload or marginal/low cardiac output. Patients admitted with significant worsening of renal function should be considered for a reduction in, or temporary discontinuation of ACE inhibitors, ARBs, and/or aldosterone antagonists until renal function improves. Although it is important to ensure that evidence-based medications are instituted before hospital discharge, it is equally critical to reassess medications on admission and adjust their administration in light of the worsening HF.

8.4. Diuretics in Hospitalized Patients: Recommendations

Class I

1. Patients with HF admitted with evidence of significant fluid overload should be promptly treated with intravenous loop diuretics to reduce morbidity.375,738 (Level of Evidence: B)

2. If patients are already receiving loop diuretic therapy, the initial intravenous dose should equal or exceed their chronic oral daily dose and should be given as either intermittent boluses or continuous infusion. Urine output and signs and symptoms of congestion should be serially assessed, and the diuretic dose should be adjusted accordingly to relieve symptoms, reduce volume excess, and avoid hypotension.739 (Level of Evidence: B)

3. The effect of HF treatment should be monitored with careful measurement of fluid intake and output, vital signs, body weight that is determined at the same time each day, and clinical signs and symptoms of systemic perfusion and congestion. Daily serum electrolytes, urea nitrogen, and creatinine concentrations should be measured during the use of intravenous diuretics or active titration of HF medications. (Level of Evidence: C)

Class IIa

1. When diuresis is inadequate to relieve symptoms, it is reasonable to intensify the diuretic regimen using either:
   a. higher doses of intravenous loop diuretics38,739 (Level of Evidence: B); or
   b. addition of a second (eg, thiazide) diuretic.740–743 (Level of Evidence: B).

Class IIb

1. Low-dose dopamine infusion may be considered in addition to loop diuretic therapy to improve diuresis and better preserve renal function and renal blood flow.744,745 (Level of Evidence: B)

Patients with significant fluid overload should be initially treated with loop diuretics given intravenously during hospitalization. Therapy should begin in the emergency department without delay, as early therapy has been associated with better outcomes.37,738 Patients should be carefully monitored, including serial evaluation of volume status and systemic perfusion. Monitoring of daily weight, supine and standing vital signs, and fluid input and output is necessary for daily management. Assessment of daily electrolytes and renal function should be performed while intravenous diuretics are administered or HF medications are actively titrated. Intravenous loop diuretics have the potential to reduce glomerular filtration rate, further worsen neurohumoral activation, and produce electrolyte disturbances. Thus, although the use of diuretics may relieve symptoms, their impact on mortality has not been well studied. Diuretics should be administered at doses sufficient to achieve optimal volume status and relieve congestion without inducing an excessively rapid reduction in intravascular volume, which could result in hypotension, renal dysfunction, or both. Because loop diuretics have a relatively short half-life, sodium reabsorption in the tubules will occur once the tubular concentration of the diuretics declines. Therefore, limiting sodium intake and dosing the diuretic continuously or multiple times per day will enhance diuretic effectiveness.434,737,746–748

Some patients may present with moderate to severe renal dysfunction such that the diuretic response may be blunted, necessitating higher initial diuretic doses. In many cases, reduction of fluid overload may improve congestion and improve renal function, particularly if significant venous congestion is reduced.749 Clinical experience suggests it is difficult to determine whether congestion has been adequately treated in many patients, and registry data have confirmed that patients are frequently discharged after a net weight loss of only a few pounds. Although patients may rapidly improve symptomatically, they may remain congested or hemodynamically compromised. Routine use of serial natriuretic peptide measurement or Swan-Ganz catheter has not been conclusively shown to improve outcomes among these patients. Nevertheless, careful evaluation of all physical findings, laboratory parameters, weight change, and net fluid change should be considered before discharge.

When a patient does not respond to initial intravenous diuretics, several options may be considered. Efforts should be made to
make certain that congestion persists and that another hemodynamic profile or alternate disease process is not evident. If there is doubt about the fluid status, consideration should be given for assessment of filling pressures and cardiac output using right-heart catheterization. If volume overload is confirmed, the dose of the loop diuretic should be increased to ensure that adequate drug levels reach the kidney. Adding a second diuretic, typically a thiazide, can improve diuretic responsiveness.\textsuperscript{455,442,443} Theoretically, continuous diuretic infusion may enhance diuresis because continuous diuretic delivery to the nephron avoids rebound sodium and fluid reabsorption.\textsuperscript{440,441,750,751} However, the DOSE (Diuretic Optimization Strategies Evaluation) trial did not find any significant difference between continuous infusion versus intermittent bolus strategies for symptoms, diuresis, or outcomes.\textsuperscript{739} It is reasonable to try an alternate approach of using either bolus or continuous infusion therapy different from the initial strategy among patients who are resistant to diuretics. Finally, some data suggest that low-dose dopamine infusion in addition to loop diuretics may improve diuresis and better preserve renal function, although ongoing trials will provide further data on this effect.\textsuperscript{744}

See Online Data Supplement 17 for additional data on diuretics.

8.5. Renal Replacement Therapy—Ultrafiltration: Recommendations

Class IIb

1. Ultrafiltration may be considered for patients with obvious volume overload to alleviate congestive symptoms and fluid weight.\textsuperscript{752} (Level of Evidence: B)

2. Ultrafiltration may be considered for patients with refractory congestion not responding to medical therapy. (Level of Evidence: C)

If all diuretic strategies are unsuccessful, ultrafiltration may be considered. Ultrafiltration moves water and small- to medium-weight solutes across a semipermeable membrane to reduce volume overload. Because the electrolyte concentration is similar to plasma, relatively more sodium can be removed than by diuretics.\textsuperscript{753–755} Initial studies supporting use of ultrafiltration in HF were small but provided safety and efficacy data in acute HF.\textsuperscript{755–757} Use of ultrafiltration in HF has been shown to reduce neurohormone levels and increase diuretic responsiveness. In a larger trial of 200 unselected patients with acute HF, ultrafiltration did reduce weight compared with bolus or continuous diuretics at 48 hours, had similar effects on the dyspnea score compared with diuretics, and improved readmission rate at 90 days.\textsuperscript{755} A randomized acute HF trial in patients with cardiorenal syndrome and persistent congestion has failed to demonstrate a significant advantage of ultrafiltration over bolus diuretic therapy.\textsuperscript{758,759} Cost, the need for veno-venous access, provider experience, and nursing support remain concerns about the routine use of ultrafiltration. Consultation with a nephrologist is appropriate before initiating ultrafiltration, especially in circumstances where the non-nephrology provider does not have sufficient experience with ultrafiltration.

See Online Data Supplements 17 and 38 for additional data on diuretics versus ultrafiltration in acute decompensated HF and worsening renal function and mortality.

8.6. Parenteral Therapy in Hospitalized HF: Recommendation

Class IIb

1. If symptomatic hypotension is absent, intravenous nitroglycerin, nitroprusside, or nesiritide may be considered an adjuvant to diuretic therapy for relief of dyspnea in patients admitted with acutely decompensated HF.\textsuperscript{760–763} (Level of Evidence: A)

The different vasodilators include 1) intravenous nitroglycerin, 2) sodium nitroprusside, and 3) nesiritide. Intravenous nitroglycerin acts primarily through venodilation, lowers preload, and may help to rapidly reduce pulmonary congestion.\textsuperscript{764,765} Patients with HF and hypertension, coronary ischemia, or significant mitral regurgitation are often cited as ideal candidates for the use of intravenous nitroglycerin. However, tachyphylaxis to nitroglycerin may develop within 24 hours, and up to 20% of those with HF may develop resistance to even high doses.\textsuperscript{766–768}

Sodium nitroprusside is a balanced preload-reducing venodilator and afterload-reducing arteriodilator that also dilates the pulmonary vasculature.\textsuperscript{769} Data demonstrating efficacy are limited, and invasive hemodynamic blood pressure monitoring (such as an arterial line) is typically required; in such cases, blood pressure and volume status should be monitored frequently. Nitroprusside has the potential for producing marked hypotension and is usually used in the intensive care setting as well; longer infusions of the drug have been rarely associated with thiocyanate toxicity, particularly in the setting of renal insufficiency. Nitroprusside is potentially of value in severely congested patients with hypertension or severe mitral valve regurgitation complicating LV dysfunction.

Nesiritide (human BNP) reduces LV filling pressure but has variable effects on cardiac output, urinary output, and sodium excretion. An initial study demonstrated that the severity of dyspnea is reduced more rapidly compared with diuretics alone.\textsuperscript{760} A large randomized trial in patients with acute decompensated HF demonstrated nesiritide had no impact on mortality, rehospitalization, or renal function, a small but statistically significant impact on dyspnea, and an increased risk of hypotension.\textsuperscript{762} Because nesiritide has a longer effective half-life than nitroglycerin or nitroprusside, adverse effects such as hypotension may persist longer. Overall, presently there are no data that suggest that intravenous vasodilators improve outcomes in the patient hospitalized with HF; as such, use of intravenous vasodilators is limited to the relief of dyspnea in the hospitalized HF patient with intact blood pressure. Administration of intravenous vasodilators in patients with HFpEF should be done with caution because these patients are typically more volume sensitive.

The use of inotropic support as indicated for hospitalized HF with shock or impending shock and/or end-organ perfusion limitations is addressed in Section 7.4.4. See Table 26 for drug therapies and Online Data Supplements 32 and 33 for additional information on inotropic support.

See Online Data Supplement 39 for additional data on nesiritide.
8.7. Venous Thromboembolism Prophylaxis in Hospitalized Patients: Recommendation

Class I

1. A patient admitted to the hospital with decompensated HF should receive venous thromboembolism prophylaxis with an anticoagulant medication if the risk–benefit ratio is favorable.21,770 (Level of Evidence: B)

HF has long been recognized as affording additional risk for venous thromboembolic disease, associated with a number of pathophysiologic changes, including reduced cardiac output, increased systemic venous pressure, and chemical changes promoting blood clotting. When patients are hospitalized for decompensated HF or when patients with chronic stable HF are hospitalized for other reasons, they are at increased risk for venous thromboembolic disease, although accurate numerical estimates are lacking in the literature.

Most early data on the effectiveness of different anticoagulant regimens to reduce the incidence of venous thromboembolic disease in hospitalized patients were either observational, retrospective reports776,777 or prospective studies using a variety of drugs and differing definitions of therapeutic effect and endpoints,774,778–780 making summary conclusions difficult. Early studies involved patients with far longer hospital lengths of stay than occur presently and were performed well before present standard-of-care treatments and diagnostic tests were available.774,776–780 Newer trials using presently available antithrombotic drugs often were not limited to patients with HF but included those with other acute illnesses, severe respiratory diseases, or simply a broad spectrum of hospitalized medical patients.771–774,781 In most studies, patients were categorized as having HF by admitting diagnosis, clinical signs, or functional class, whereas only 1 study provided LVEF data on enrolled study patients. All included trials tried to exclude patients perceived to have an elevated risk of bleeding complications or with an elevated risk of toxicity from the specific agent tested (eg, enoxaparin in patients with compromised renal function). Patients with HF typically made up a minority of the study cohort, and significance of results were not always reported by the authors, making ACCF/AHA class I recommendations difficult to support using this guideline methodology. In some trials, concurrent aspirin was allowed but not controlled for as a confounding variable.772,783

For patients admitted specifically for decompensated HF and with adequate renal function (serum creatinine <2.0 mg/dL), randomized trials suggest that enoxaparin 40 mg subcutaneously once daily770,773,774,783 or unfractionated heparin 5000 units subcutaneously every 8 hours771 will reduce radiographically demonstrable venous thrombosis. Effects on mortality or clinically significant pulmonary embolism rates are unclear. Lower doses of enoxaparin do not appear superior to placebo,770,773 whereas continuing weight-based enoxaparin therapy up to 3 months after hospital discharge does not appear to provide additional benefit.782

A single prospective study failed to demonstrate certoparin to be noninferior to unfractionated heparin,783 whereas retrospective analysis of a prospective trial of dalteparin was underpowered to determine benefit in its HF cohort.776 Fondaparinux failed to show significant difference from placebo in an RCT that included a subgroup of 160 patients with HF.781

No adequate trials have evaluated anticoagulant benefit in patients with chronic but stable HF admitted to the hospital for other reasons. However, the MEDENOX (Medical Patients with Enoxaparin) trial suggested that the benefit of enoxaparin may extend to this population.770,773,774

A systematic review failed to demonstrate prophylactic efficacy of graded compression stockings in general medical patients, but significant cutaneous complications were associated with their use. No studies were performed exclusively on patients with HF. Two RCTs in patients with stroke found no efficacy of these devices.785,786

See Online Data Supplement 20 for additional data on anticoagulation.

8.8. Arginine Vasopressin Antagonists: Recommendation

Class IIb

1. In patients hospitalized with volume overload, including HF, who have persistent severe hyponatremia and are at risk for or having active cognitive symptoms despite water restriction and maximization of GDMT, vasopressin antagonists may be considered in the short term to improve serum sodium concentration in hypervolemic, hyponatremic states with either a V2 receptor selective or a nonselective vasopressin antagonist.787,788 (Level of Evidence: B)

Even mild hyponatremia may be associated with neurocognitive problems, including falls and attention deficits.789 Treatment of hypervolemic hyponatremia with a V2-selective vasopressin antagonist (tolvaptan) was associated with a significant improvement in the mental component of the Medical Outcomes Study Short Form General Health Survey.788 Hyponatremia may be treated with water restriction and maximization of GDMT that modulate angiotensin II, leading to improved renal perfusion and decreased thirst. Alternative causes of hyponatremia (eg, syndrome of inappropriate antidiuretic hormone, hypothyroidism, and hypoaldosteronism) should be assessed. Vasopressin antagonists improve serum sodium in hypervolemic, hyponatremic states; however, longer-term therapy with a V2-selective vasopressin antagonist did not improve mortality in patients with HF.790,791 Currently, 2 vasopressin antagonists are available for clinical use: conivaptan and tolvaptan. It may be reasonable to use a nonselective vasopressin antagonist to treat hyponatremia in patients with HF with cognitive symptoms due to hyponatremia. However, the long-term safety and benefit of this approach remains unknown. A summary of the recommendations for the hospitalized patient appears in Table 28.

8.9. Inpatient and Transitions of Care: Recommendations

See Table 29 for a summary of recommendations from this section.

Class I

1. The use of performance improvement systems and/or evidence-based systems of care is recommended in the hospital and early postdischarge outpatient setting to...
identify appropriate HF patients for GDMT, provide clinicians with useful reminders to advance GDMT, and assess the clinical response.82,365,792–796  

(Level of Evidence: B)

2. Throughout the hospitalization as appropriate, before hospital discharge, at the first postdischarge visit, and in subsequent follow-up visits, the following should be addressed.204,795,797–799  

(Level of Evidence: B):  

a. initiation of GDMT if not previously established and not contraindicated;  

b. precipitant causes of HF, barriers to optimal care transitions, and limitations in postdischarge support;

---

COR indicates Class of Recommendation; GDMT, guideline-directed medical therapy; HF, heart failure; and LOE, Level of Evidence.
c. assessment of volume status and supine/upright hypotension with adjustment of HF therapy as appropriate;
d. titration and optimization of chronic oral HF therapy;
e. assessment of renal function and electrolytes where appropriate;
f. assessment and management of comorbid conditions;
g. reinforcement of HF education, self-care, emergency plans, and need for adherence; and
h. consideration for palliative care or hospice care in selected patients.

3. Multidisciplinary HF disease-management programs are recommended for patients at high risk for hospital readmission, to facilitate the implementation of GDMT, to address different barriers to behavioral change, and to reduce the risk of subsequent rehospitalization for HF.\textsuperscript{82,808-809} (Level of Evidence: B)

Class IIa

1. Scheduling an early follow-up visit (within 7 to 14 days) and early telephone follow-up (within 3 days) of hospital discharge are reasonable.\textsuperscript{101,803} (Level of Evidence: B)

2. Use of clinical risk-prediction tools and/or biomarkers to identify patients at higher risk for postdischarge clinical events are reasonable.\textsuperscript{215} (Level of Evidence: B)

Decisions about pharmacological therapies delivered during hospitalization likely can impact postdischarge outcome. Continuation or initiation of HF GDMT prior to hospital discharge is associated with substantially improved clinical outcomes for patients with HF/EF. However, caution should be used when initiating beta blockers in patients who have required inotropes during their hospital course or when initiating ACE inhibitors, ARBs, or aldosterone antagonists in those patients who have experienced marked azotemia or are at risk for hyperkalemia. The patient should be transitioned to oral diuretic therapy to verify its effectiveness. Similarly, optimal volume status should be achieved. Blood pressure should be adequately controlled, and, in patients with AF, ventricular response should also be well controlled. The hospitalization is a “teachable moment” to reinforce patient and family education and develop a plan of care, which should be communicated to the appropriate healthcare team.

Safety for patients hospitalized with HF is crucial. System changes necessary to achieve safer care include the adoption by all US hospitals of a standardized set of 30 “Safe Practices” endorsed by the National Quality Forum\textsuperscript{804} and National Patient Safety Goals espoused by The Joint Commission.\textsuperscript{805} Improved communication between clinicians and nurses, medication reconciliation, carefully planned transitions between care settings, and consistent documentation are examples of patient safety standards that should be ensured for patients with HF discharged from the hospital.

The prognosis of patients hospitalized with HF, and especially those with serial readmissions, is suboptimal. Hence, appropriate levels of symptomatic relief, support, and palliative care for patients with chronic HF should be addressed as an ongoing key component of the plan of care, especially when patients are hospitalized with acute decompensation.\textsuperscript{806}

The appropriateness of discussion about advanced therapy or end-of-life preferences is reviewed in Section 11.

For patients with HF, the transition from inpatient to outpatient care can be an especially vulnerable period because of the progressive nature of the disease state, complex medical regimens, the large number of comorbid conditions, and the multiple clinicians who may be involved. Patient education and written discharge instructions or educational material given to the patient, family members, and/or caregiver during the hospital stay or at discharge to home are essential components of transition care. These should address all of the following: activity level, diet, discharge medications, follow-up appointment, weight monitoring, and what to do if symptoms worsen.\textsuperscript{297} Thorough discharge planning that includes special emphasis on ensuring adherence to an evidence-based medication regimen\textsuperscript{805} is associated with improved patient outcomes.\textsuperscript{792,797,807} More intensive delivery of discharge instructions, coupled tightly with subsequent well-coordinated follow-up care for patients hospitalized with HF; has produced positive results in several studies.\textsuperscript{72,793,800} The addition of a 1-hour, nurse educator–delivered teaching session at the time of hospital discharge, using standardized instructions, resulted in improved clinical outcomes, increased self-care and treatment adherence, and reduced cost of care. Patients receiving the education intervention also had a lower risk of rehospitalization or death and lower costs of care.\textsuperscript{365} There are ongoing efforts to further develop evidence-based interventions in this population.

Transitional care extends beyond patient education. Care information, especially changes in orders and new diagnostic information, must be transmitted in a timely and clearly understandable form to all of the patient’s clinicians who will be delivering follow-up care. Other important components of transitional care include preparation of the patient and caregiver for what to expect at the next site of care, reconciliation of medications, follow-up plans for outstanding tests, and discussions about monitoring signs and symptoms of worsening conditions. Early outpatient follow-up, a central element of transitional care, varies significantly across US hospitals. Early postdischarge follow-up may help minimize gaps in understanding of changes to the care plan or knowledge of test results and has been associated with a lower risk of subsequent rehospitalization.\textsuperscript{803} A follow-up visit within 7 to 14 days and/or a telephone follow-up within 3 days of hospital discharge are reasonable goals of care.

See Online Data Supplement 40 for additional data on oral medications for the hospitalized patient.

9. Important Comorbidities in HF

9.1. Atrial Fibrillation\textsuperscript{§}

Patients with HF are more likely than the general population to develop AF.\textsuperscript{808} There is a direct relationship between the NYHA class and prevalence of AF in patients with HF progressing from 4% in those who are NYHA class I to 40% in those who are NYHA class IV.\textsuperscript{809} AF is also a strong independent risk factor for subsequent development of HF.\textsuperscript{176,808} In addition to those

\textsuperscript{§}The “ACC/AHA/ESC 2006 Guidelines for the Management of Patients With Atrial Fibrillation” and the 2 subsequent focused updates from 2011-14 are considered policy at the time of publication of the present HF Guideline; however, a fully revised AF guideline, which will include updated recommendations on AF, is in development, with publication expected in 2013 or 2014.

Type IC refers to the Vaughan Williams classification of antiarrhythmic drugs.
AF indicates atrial fibrillation; AV, atrioventricular; ECG, electrocardiogram; LA, left atrial; LV, left ventricular; MI, myocardial infarction; RA, right atrial; and RV, right ventricular.

Reproduced from Fuster et al.6

with HFrEF, patients with HFrEF are also at greater risk for AF than the general age-matched population.811 HF and AF can interact to promote their perpetuation and worsening through mechanisms such as rate-dependent worsening of cardiac function, fibrosis, and activation of neurohumoral vasoconstrictors. AF can worsen symptoms in patients with HF, and, conversely, worsened HF can promote a rapid ventricular response in AF.

Similar to other patient populations, for those with AF and HF, the main goals of therapy are prevention of thromboembolism and symptom control. Most patients with AF and HF would be expected to be candidates for systemic anticoagulation unless otherwise contraindicated. General principles of management include correction of underlying causes of AF and HF as well as optimization of HF management (Table 30). As in other patient populations, the issue of rate control versus rhythm control has been investigated. For patients who develop HF as a result of AF, a rhythm control strategy should be pursued. It is important to recognize that AF with a rapid ventricular response is one of the few potentially reversible causes of HF. Because of this, a patient who presents with newly detected HF in the presence of AF with a rapid ventricular response should be presumed to have a rate-related cardiomyopathy until proven otherwise. In this situation, 2 strategies can be considered. One is rate control of the patient’s AF and see if HF and EF improve. The other is to try to restore and maintain sinus rhythm. In this situation, it is common practice to initiate amiodarone and then arrange for cardioversion 1 month later. Amiodarone has the advantage of being both an effective rate-control medication and the most effective antiarrhythmic medication with a lower risk of proarrhythmic effect.

In patients with HF who develop AF, a rhythm-control strategy has not been shown to be superior to a rate-control strategy.812 If rhythm control is chosen, limited data suggest that AF catheter ablation in HF patients may lead to improvement in LV function and quality of life but is less likely to be effective than in patients with intact cardiac function.813,814 Because of their favorable effect on morbidity and mortality in patients with systolic HF, beta-adrenergic blockers are the preferred agents for achieving rate control unless otherwise contraindicated.
Pharmacologic management of the patient with newly discovered AF

Paroxysmal

No therapy needed unless significant symptoms (e.g., hypotension, HF, angina pectoris)

Anticoagulation as needed

Persistent

Accept permanent AF

Anticoagulation and rate control as needed

Rate control and anticoagulation as needed

Consider antiarrhythmic drug therapy

Cardioversion

Long-term antiarrhythmic drug therapy as necessary

Pharmacologic management of the patient with recurrent paroxysmal AF

Minimal or no symptoms

Anticoagulation and rate control as needed

No drug for prevention of AF

Disabling symptoms in AF

Anticoagulation and rate control as needed

Antiarrhythmic therapy

AF ablation if antiarrhythmic therapy treatment fails

Figure 5. Pharmacological management of patients with newly discovered AF. AF indicates atrial fibrillation; and HF, heart failure. Reproduced from Fuster et al.®

Figure 6. Pharmacological management of patients with recurrent paroxysmal AF. AF indicates atrial fibrillation. Reproduced from Fuster et al.®
Digoxin may be an effective adjunct to a beta blocker. The non-dihydropyridine calcium antagonists, such as diltiazem, should be used with caution in those with depressed EF because of their negative inotropic effect. For those with HFpEF, nondihydropyridine calcium antagonists can be effective for achieving rate control but may be more effective when used in combination with digoxin. For those for whom a rate-control strategy is chosen, when rate control cannot be achieved either because of drug inefficacy or intolerance, atrioventricular node ablation and CRT device placement can be useful.842,843 See Figures 5 and 6 for AF treatment algorithms.

See Online Data Supplement 41 for additional data on AF.

9.2. Anemia

Anemia is a common finding in patients with chronic HF. Although variably reported, in part due to the lack of consensus on the definition of anemia, the prevalence of anemia among patients with HF increases with HF severity. Anemia is also more common in women and is seen in both patients with HFpEF and HFrEF.818-823 The World Health Organization defines anemia as a hemoglobin level of <12 g/dL in women and <13 g/dL in men. Registries have reported anemia to be present in 25% to 40% of HF patients.818-820 Anemia is associated with an increased mortality risk in HF. In a large study of >150,000 patients, the mortality risk was approximately doubled in anemic HF patients compared with those without anemia, and this risk persisted after controlling for other confounders, including renal dysfunction and HF severity.818 Anemia is also associated with reduced exercise capacity, impaired HRQOL, and a higher risk for hospitalization.823-825,828 These risks are inversely and linearly associated with hemoglobin levels, although a U-shaped risk with the highest hemoglobin levels has been reported.824,825

Multiple etiological factors, many of which coexist within individual patients, contribute to the development of anemia in HF. Anemia in patients with HF is often normocytic and accompanied by an abnormally low reticulocyte count.825,827 Evaluation of anemia in HF requires careful consideration of other causes, the most common being secondary causes of iron deficiency anemia.

In persons without identifiable causes of anemia, erythropoiesis-stimulating agents have gained significant interest as potential adjunctive therapy in the patient with HF. In a retrospective study of erythropoiesis-stimulating agents in 26 patients with HF and anemia, the hemoglobin level, LVEF, and functional class improved.828 These patients required lower diuretic doses and were hospitalized less often. Similar findings were also observed in a randomized open-label study of 32 patients.829 A single-blind RCT showed that erythropoietin increased hemoglobin, peak oxygen uptake, and exercise duration in patients with severe HF and anemia.830 Two further studies confirmed these findings; however, none of these were double blind.831,832

These positive data led to 2 larger studies. A 165-patient study showed that darbepoetin alfa was associated with improvement in several HRQOL measures with a trend toward improved exercise capacity (6-minute walking distance +34±7 m versus +11±10 m, P=0.074).831 In STAMINA-HeFT (Study of Anemia in Heart Failure Trial), 319 patients were randomly assigned to darbepoetin alfa or placebo for 12 months.834 Although darbepoetin alfa did not improve exercise duration, it was well tolerated, and a trend toward improvement in the composite endpoint of all-cause mortality or first hospitalization for HF was seen (hazard ratio: 0.68; 95% confidence interval: 0.43 to 1.08; P=0.10).834 These favorable data led to the design and initiation of the RED-HF (Phase III Reduction of Events With Darbepoetin alfa in Heart Failure) trial.835

Two trials in erythropoiesis-stimulating agents, however, later raised concerns that patients treated with an erythropoiesis-stimulating agent may have an increased risk of cardiovascular events.836,837 Because the populations in these trials differed, the RED-HF trial was continued. Nevertheless, at the completion of the trial, the investigators concluded that treatment with darbepoetin alfa did not improve clinical outcomes in patients with systolic HF and mild-to-moderate anemia.838 Finally, a trial using intravenous iron as a supplement in patients with HFpEF with iron deficiency showed an improvement in functional status.840 There were no untoward adverse effects of iron in this trial. In the absence of a definitive evidence base, the writing committee has deferred a specific treatment recommendation regarding anemia.

9.3. Depression

Depression is common in patients with HF; those with depressive symptoms have lower HRQOL, poorer self-care, worse clinical outcomes, and more use of healthcare services.841-843 Although it might be assumed that depression occurs only among hospitalized patients,844 a multicenter study demonstrated that even at least 3 months after a hospitalization, 63% of patients with HF reported symptoms of depression.845 Potential pathophysiologic mechanisms proposed to explain the high prevalence of depression in HF include autonomic nervous system dysfunction, inflammation, cardiac arrhythmias, and altered platelet function, but the mechanism remains unclear.846 Although remission from depression may improve cardiovascular outcomes, the most effective intervention strategy is not yet known.842

9.4. Other Multiple Comorbidities

Although there are additional and important comorbidities that affect patients with HF as shown in Table 31, how best to generate specific recommendations remains uncertain, given the status of current evidence.

10. Surgical/Percutaneous/Transcatheter Interventional Treatments of HF: Recommendations

See Table 32 for a summary of recommendations from this section.

Class I

1. Coronary artery revascularization via CABG or percutaneous intervention is indicated for patients (HFpEF and HFrEF) on GDMT with angina and suitable coronary anatomy, especially for a left main stenosis (>50%) or left main equivalent disease.90,12,34,448 (Level of Evidence: C)

Class IIa

1. CABG to improve survival is reasonable in patients with mild to moderate LV systolic dysfunction (EF
35% to 50%) and significant (≥70% diameter stenosis) multivessel CAD or proximal left anterior descending coronary artery stenosis when viable myocardium is present in the region of intended revascularization. (Level of Evidence: B)

2. CABG or medical therapy is reasonable to improve morbidity and cardiovascular mortality for patients with severe LV dysfunction (EF <35%), HF, and significant CAD. (Level of Evidence: B)

3. Surgical aortic valve replacement is reasonable for patients with critical aortic stenosis and a predicted surgical mortality of no greater than 10%. (Level of Evidence: B)

4. Transcatheter aortic valve replacement after careful candidate consideration is reasonable for patients with critical aortic stenosis who are deemed inoperable. (Level of Evidence: B)

Class IIb

1. CABG may be considered with the intent of improving survival in patients with ischemic heart disease with severe LV systolic dysfunction (EF <35%) and operable coronary anatomy whether or not viable myocardium is present. (Level of Evidence: B)

2. Transcatheter mitral valve repair or mitral valve surgery for functional mitral insufficiency is of uncertain benefit and should only be considered after careful candidate selection and with a background of GDMT. (Level of Evidence: B)

CABG indicates coronary artery bypass graft; CAD, coronary artery disease; COR, Class of Recommendation; EF, ejection fraction; GDMT, guideline-directed medical therapy; HF, heart failure; HF/EF, heart failure with reduced ejection fraction; LAD, left anterior descending; LOE, Level of Evidence; and LV, left ventricular.
3. Surgical reverse remodeling or LV aneurysmectomy may be considered in carefully selected patients with HFpEF for specific indications, including intractable HF and ventricular arrhythmias.\(^8^{58}\) (Level of Evidence: B)

Surgical therapies and percutaneous interventions that are commonly integrated, or at least considered, in HF management include coronary revascularization (eg, CABG, angioplasty, stenting); aortic valve replacement; mitral valve replacement or repair; septal myectomy or alcohol septal ablation for hypertrophic cardiomyopathy; surgical ablation of ventricular arrhythmia; MCS; and cardiac transplantation.\(^575,683,879,860\) Surgical placement of ICDs or LV pacing leads is of historical importance but may be considered in situations where transvenous access is not feasible.

The most common reason for intervention is CAD. Myocardial viability indicates the likelihood of improved outcomes with either surgical or medical therapy but does not identify patients with greater survival benefit from revascularization.\(^8^{54}\) The dictum of CABG for left main CAD and reduced LV function was considered absolute and subsequently extrapolated to all severities of LV dysfunction without a confirmatory evidence base.\(^8^{48}\) Newer studies have addressed patients with multi-vessel CAD, HF, and at least moderately severe to severe LV systolic dysfunction.\(^8^{61,862}\) Both surgical and medical therapies have similar outcomes, and decisions about revascularization should be made jointly by the HF team and cardiothoracic surgeon. The most important considerations in the decision to proceed with a surgical or interventional approach include coronary anatomy that is amenable to revascularization and appropriate concomitant GDMT. Valvular heart disease is not an infrequent cause of HF; however, when valvular disease is managed correctly and pre-emptively, its adverse consequences on ventricular mechanics can be ameliorated.

The advent of effective transcatheter approaches to both mitral and aortic disease creates the need for greater considerations of structural interventions for patients with LV systolic dysfunction and valvular heart disease. To date, the surgical or transcatheter management of functional mitral insufficiency has not been proven superior to medical therapy. A decision to intervene in functional mitral regurgitation should be made on a case-by-case basis, and consideration should be given to participation in clinical trials and/or databases. The surgical or transcatheter management of critical aortic stenosis is an effective strategy with reasonable outcomes noted even in patients with advanced age (>80 years). Indications for other surgical or percutaneous interventions in the setting of HF are driven by other relevant guidelines or other sections of this guideline, including myomectomy for hypertrophic cardiomyopathy, surgical or electrophysiological procedures for AF, nondurable or durable MCS, and heart transplantation.

Several procedures under evaluation hold promise but are not yet appropriate for a guideline-driven indication (Table 33). This includes revascularization as a means to support cellular regenerative therapies. For patients willing to consider regenerative technologies, the ideal strategy is referral to an enrolling clinical trial at a center experienced in both high-risk revascularization and cell-based science.\(^8^{63–65}\) Surgical reverse-ventricular remodeling (ventricular reconstruction) does not appear to be of benefit but may be considered in carefully selected patients with HFpEF for specified indications, including retractable HF and ventricular arrhythmias.\(^8^{58}\)

Surgical/Percutaneous/Transcatheter Interventions Under Evaluation in Patients With HF

1. Transcatheter intervention for functional mitral insufficiency             | 854–857    |
2. Left atrial resection/left atrial appendage removal, surgical or percutaneous, for AF | 867       |
3. MCS for advanced HF as a bridge to recovery                                | 868, 869   |

AF indicates atrial fibrillation; HF, heart failure; and MCS, mechanical circulatory support.

### 11. Coordinating Care for Patients With Chronic HF

#### 11.1. Coordinating Care for Patients With Chronic HF: Recommendations

**Class I**

1. Effective systems of care coordination with special attention to care transitions should be deployed for every patient with chronic HF that facilitate and ensure effective care that is designed to achieve GDMT and prevent hospitalization.\(^8^{62,79,876–884}\) (Level of Evidence: B)

2. Every patient with HF should have a clear, detailed, and evidence-based plan of care that ensures the achievement of GDMT goals, effective management of comorbid conditions, timely follow-up with the healthcare team, appropriate dietary and physical activities, and compliance with secondary prevention guidelines for cardiovascular disease. This plan of care should be updated regularly and made readily available to all members of each patient’s healthcare team.\(^13\) (Level of Evidence: C)

3. Palliative and supportive care is effective for patients with symptomatic advanced HF to improve quality of life.\(^8^{65–888}\) (Level of Evidence: B)

Education, support, and involvement of patients with HF and their families are critical and often complex, especially during transitions of care. Failure to understand and follow a detailed and often nuanced plan of care likely contributes to the high rates of HF 30-day rehospitalization and mortality seen across the United States.\(^61,889\) One critical intervention to ensure effective care coordination and transition is the provision of a comprehensive plan of care, with easily understood,
11.2. Systems of Care to Promote Care Coordination for Patients With Chronic HF

Improved communication between clinicians and nurses, medication reconciliation, carefully planned transitions between care settings, and consistent documentation are examples of patient safety standards that should be ensured for all patients with HF. The National Quality Forum has also endorsed a set of patient-centered “Preferred Practices for Care Coordination,” which detail comprehensive specifications for successful care coordination for patients and their families.

Systems of care designed to support patients with HF and other cardiac diseases can produce a significant improvement in outcomes. Furthermore, the Centers for Medicare and Medicaid Services is now financially penalizing hospitals for avoidable hospitalizations and readmissions, thereby emphasizing the importance of such systems-based care coordination of patients with HF. However, the quality of evidence is mixed for specific components of HF clinical management interventions, such as home-based care, disease management and remote telemonitoring programs. Unfortunately, numerous and nonstandardized definitions of disease management including the specific elements that compose disease management, impede efforts to improve the care of patients with HF. Hence, more generic multidisciplinary strategies for improving the quality and cost-effectiveness of systems-based HF care should be evaluated with equal weight to those interventions focused on improving adherence to GDMT. For example, multidisciplinary approaches can reduce rates of hospitalization for HF. Programs involving specialized follow-up by a multidisciplinary team decrease all-cause hospitalizations and mortality; however, this has not been shown for “disease management programs” that focus only on self-care activities. Furthermore, patient characteristics may be important predictors of HF and other cardiac disease–related survival and hospitalization. Overall, very few specific interventions have been consistently identified and successfully applied in clinical practice.

See Online Data Supplements 42 and 43 for additional data on disease management and telemonitoring.

11.3. Palliative Care for Patients With HF

The core elements of comprehensive palliative care for HF delivered by clinicians include expert symptom assessment and management. Ongoing care should address symptom control, psychosocial distress, HRQOL, preferences about end-of-life care, caregiver support, and assurance of access to evidence-based disease-modifying interventions. The HF team can help patients and their families explore treatment options and prognosis. The HF and palliative care teams are best suited to help patients and families decide when end-of-life care (including hospice) is appropriate. Assessment for frailty and dementia is part of this decision care process offered to the patient and family.

Data suggest that advance directives specifying limitations in end-of-life care are associated with significantly lower levels of Medicare spending, lower likelihood of in-hospital death, and higher use of hospice care in regions characterized by higher levels of end-of-life spending. In newly diagnosed cancer patients, palliative care interventions delivered early have had a positive impact on survival and HRQOL. This approach may also be relevant for HF. Access to formally trained palliative care specialists may be limited in ambulatory settings. Therefore, cardiologists, primary care physicians, physician assistants, advanced practice nurses, and other members of the HF healthcare team should be familiar with these local treatment options. Evaluation for cardiac transplantation or MCS in experienced centers should include formal palliative care consultation, which can improve advanced care planning and enhance the overall quality of decision making and integrated care for these patients, regardless of the advanced HF therapy selected.

12. Quality Metrics/Performance Measures: Recommendations

Class I

1. Performance measures based on professionally developed clinical practice guidelines should be used with the goal of improving quality of care for HF.

(Level of Evidence: B)

Class IIa

1. Participation in quality improvement programs and patient registries based on nationally endorsed, clinical practice guideline–based quality and performance measures can be beneficial in improving the quality of HF care.

(Level of Evidence: B)

Quality measurement and accountability have become integral parts of medical practice over the past 2 decades. HF has been a specific target of quality measurement, improvement, and reporting because of its substantial impact on population morbidity and mortality. Commonly used performance measures for HF can be considered in 2 distinct categories: process measures and outcomes measures. Process performance measures focus on the aspects of care that are delivered to a patient (eg, the prescription of a particular drug such as an ACE inhibitor in patients with LV systolic dysfunction and without contraindications). Process measures derive from the most definitive guideline recommendations (ie, class I and class III recommendations). A small group of process measures for hospitalized patients with HF have...

ACCF indicates American College of Cardiology Foundation; ACCP, American College of Chest Physicians; ACE, angiotensin-converting enzyme; ADA, American Diabetes Association; AHA, American Heart Association; ARB, angiotensin-receptor blocker; ATS, American Thoracic Society; CPR, cardiopulmonary resuscitation; CRT, cardiac resynchronization therapy; ERS, European Respiratory Society; HF, heart failure; HHS, Health and Human Services; ICD, implantable cardioverter-defibrillator; JNC, Joint National Committee; MCS, mechanical circulatory support; NQF, National Quality Forum; QOL, quality of life; and SIHD, stable ischemic heart disease.
HF indicates heart failure; and NQF, National Quality Forum.

been reported to the public by the Centers for Medicare and Medicaid Services as part of the Hospital Compare program.918

Measures used to characterize the care of patients with HF should be those developed in a multiorganizational consensus process using an explicit methodology focusing on measurability, validity, reliability, feasibility, and ideally, correlation with patient outcomes,919,920 and with transparent disclosure and management of possible conflicts of interest.

In the case of HF, several national outcome measures are currently in use (Table 35), and the ACCF/AHA/American Medical Association–Physician Consortium for Performance Improvement recently published revised performance measures document includes several process measures for both inpatient and outpatient HF care (Table 36).921 Of note, the ACCF/AHA distinguish between processes of care that can be considered “Performance Measures” (ie, suitable for use for accountability purposes) and “Quality Metrics” (ie, suitable for use for quality improvement but not accountability).922

Measures are appealing for several reasons; by definition, they reflect the strongest guideline recommendations. When appropriately specified, they are relatively easy to calculate and

<table>
<thead>
<tr>
<th>Measure Description*</th>
<th>Care Setting</th>
<th>Level of Measurement</th>
</tr>
</thead>
<tbody>
<tr>
<td>1. LVEF assessment</td>
<td>Percentage of patients aged ≥18 y with a diagnosis of HF for whom the quantitative or qualitative results of a recent or prior (any time in the past) LVEF assessment is documented within a 12-mo period</td>
<td>Outpatient</td>
</tr>
<tr>
<td>2. LVEF assessment</td>
<td>Percentage of patients aged ≥18 y with a principal discharge diagnosis of HF with documentation in the hospital record of the results of an LVEF assessment performed either before arrival or during hospitalization, OR documentation in the hospital record that LVEF assessment is planned for after discharge</td>
<td>Inpatient</td>
</tr>
<tr>
<td>3. Symptom and activity assessment</td>
<td>Percentage of patient visits for those patients aged ≥18 y with a diagnosis of HF with quantitative results of an evaluation of both current level of activity and clinical symptoms documented</td>
<td>Outpatient</td>
</tr>
<tr>
<td>4. Symptom management†</td>
<td>Percentage of patient visits for those patients aged ≥18 y with a diagnosis of HF and with quantitative results of an evaluation of both level of activity and clinical symptoms documented in which patient symptoms have improved or remained consistent with treatment goals since last assessment OR patient symptoms have demonstrated clinically important deterioration since last assessment with a documented plan of care</td>
<td>Outpatient</td>
</tr>
<tr>
<td>5. Patient self-care education†‡</td>
<td>Percentage of patients aged ≥18 y with a diagnosis of HF who were provided with self-care education on ≥3 elements of education during ≥1 visits within a 12-mo period</td>
<td>Outpatient</td>
</tr>
<tr>
<td>6. Beta-blocker therapy for LVSD (outpatient and inpatient setting)</td>
<td>Percentage of patients aged ≥18 y with a diagnosis of HF with a current or prior LVEF &lt;40% who were prescribed beta-blocker therapy with bisoprolol, carvedilol, or sustained-release metoprolol succinate either within a 12-mo period when seen in the outpatient setting or at hospital discharge</td>
<td>Inpatient and outpatient</td>
</tr>
<tr>
<td>7. ACE inhibitor or ARB therapy for LVSD (outpatient and inpatient setting)</td>
<td>Percentage of patients aged ≥18 y with a diagnosis of HF with current or prior LVEF &lt;40% who were prescribed ACE inhibitor or ARB therapy either within a 12-mo period when seen in the outpatient setting or at hospital discharge</td>
<td>Inpatient and outpatient</td>
</tr>
<tr>
<td>8. Counseling about ICD implantation for patients with LVSD on combination medical therapy†‡</td>
<td>Percentage of patients aged ≥18 y with a diagnosis of HF with current LVEF ≤35% despite ACE inhibitor/ARB and beta-blocker therapy for at least 3 mo who were counseled about ICD implantation as a treatment option for the prophylaxis of sudden death</td>
<td>Outpatient</td>
</tr>
<tr>
<td>9. Postdischarge appointment for HF patients</td>
<td>Percentage of patients, regardless of age, discharged from an inpatient facility to ambulatory care or home health care with a principal discharge diagnosis of HF for whom a follow-up appointment was scheduled and documented, including location, date, and time for a follow-up office visit or home health visit (as specified)</td>
<td>Inpatient</td>
</tr>
</tbody>
</table>
they provide a clear target for improvement. However, they do not capture the broader range of care; they apply only to those patients without contraindications to therapy. Evidence of the relation between better performance with respect to process measures and patient outcomes is conflicting, and performance rates for those measures that have been used as part of public reporting programs are generally high for all institutions, limiting the ability of these measures to identify high- and low-performing centers.

These limitations of process measures have generated interest in the use of outcomes measures as a complementary approach to characterize quality. With respect to HF, 30-day mortality and 30-day readmission are reported by the Centers for Medicare and Medicaid Services as part of the Hospital Compare program (Table 35) and are incorporated in the Centers for Medicare and Medicaid Services value-based purchasing program.\textsuperscript{913} Outcomes measures are appealing because they apply universally to almost all patients, and they provide a perspective on the performance of health systems.\textsuperscript{923} On the other hand, they are limited by the questionable adequacy of risk adjustment and by the challenges of improvement. The ACCF and AHA have published criteria that characterize the necessary attributes of robust outcomes measures.\textsuperscript{924}

See Online Data Supplement 44 for additional data on quality metrics and performance measures.

13. Evidence Gaps and Future Research Directions

Despite the objective evidence compiled by the writing committee on the basis of hundreds of clinical trials, there are huge gaps in our knowledge base about many fundamental aspects of HF care. Some key examples include an effective management strategy for patients with HFpEF beyond blood pressure control; a convincing method to use biomarkers in the optimization of medical therapy; the recognition and treatment of cardiorenal syndrome; and the critical need for improving patient adherence to therapeutic regimens. Even the widely embraced dictum of sodium restriction in HF is not well supported by current evidence. Moreover, the majority of the clinical trials that inform GDMT were designed around the primary endpoint of mortality, so that there is less certainty about the impact of therapies on the HRQOL of patients. It is also of major concern that the majority of RCTs failed to randomize a sufficient number of the elderly, women, and underrepresented minorities, thus, limiting insight into these important patient cohorts. A growing body of studies on patient-centered outcomes research is likely to address some of these deficiencies, but time will be required.

HF is a syndrome with a high prevalence of comorbidities and multiple chronic conditions, but most guidelines are developed for patients with a single disease. Nevertheless, the coexistence of additional diseases such as arthritis, renal insufficiency, diabetes mellitus, or chronic lung disease with the HF syndrome should logically require a modification of treatment, outcome assessment, or follow-up care. About 25\% of Americans have multiple chronic conditions; this figure rises to 75\% in those >65 years of age, including the diseases referred to above, as well as asthma, hypertension, cognitive disorders, or depression.\textsuperscript{847} Most RCTs in HF specifically excluded patients with significant other comorbidities from enrollment, thus limiting our ability to generalize our recommendations to many real-world patients. Therefore, the clinician must, as always, practice the art of using the best of the guideline recommendations as they apply to a specific patient.

Future research will need to focus on novel pharmacological therapies, especially for hospitalized HF; regenerative cell-based therapies to restore myocardium; and new device platforms that will either improve existing technologies (eg, CRT, ICD, left VAD) or introduce simpler, less morbid devices that are capable of changing the natural history of HF. What is critically needed is an evidence base that clearly identifies best processes of care, especially in the transition from hospital to home. Finally, preventing the burden of this disease through more successful risk modification, sophisticated screening, perhaps using specific omics technologies (ie, systems biology) or effective treatment interventions that reduce the progression from stage A to stage B is an urgent need.

</table>

This table represents the relationships of committee members with industry and other entities that were determined to be relevant to this document. These relationships were reviewed and updated in conjunction with all meetings and/or conference calls of the writing committee during the document development process. The table does not necessarily reflect relationships with industry at the time of publication. A person is deemed to have a significant interest in a business if the interest represents ownership of $≥5%$ of the voting stock or share of the business entity, or ownership of $≥$10,000 of the fair market value of the business entity; or if funds received by the person from the business entity exceed $5\%$ of the person’s gross income for the previous year. Relationships that exist with no financial benefit are also included for the purpose of transparency. Relationships in this table are modest unless otherwise noted.

According to the ACCF/AHA, a person has a relevant relationship if: a) The relationship or interest relates to the same or similar subject matter, intellectual property or asset, topic, or issue addressed in the document; or b) The company/entity (with whom the relationship exists) makes a drug, drug class, or device addressed in the document; or makes a competing drug or device addressed in the document; or c) The person or a member of the person’s household, has a reasonable potential for financial, professional or other personal gain or loss as a result of the issues/content addressed in the document.

Writing committee members are required to recuse themselves from voting on sections to which their specific relationships with industry and other entities may apply. Section numbers pertain to those in the full-text guideline.

*Writing committee members are required to recuse themselves from voting on sections to which their specific relationships with industry and other entities may apply. Section numbers pertain to those in the full-text guideline.

†Indicates significant relationship.

OSMB indicates Data Safety Monitoring Board; EP, electrophysiology; NYU, New York University; PARADIGM, a Multicenter, Randomized, Double-blind, Parallel Group, Active-controlled Study to Evaluate the Efficacy and Safety of LCZ696 Compared to Enalapril on Morbidity and Mortality in Patients With Chronic Heart Failure and Reduced Ejection Fraction; PI, Principal Investigator; SUNY, State University of New York; UCLA, University of California, Los Angeles; and VA, Veterans Affairs.

</table>

This table represents the relationships of reviewers with industry and other entities that were disclosed at the time of peer review and determined to be relevant to this document. It does not necessarily reflect relationships with industry at the time of publication. A person is deemed to have a significant interest in a business if the interest represents ownership of ≥5% of the voting stock or share of the business entity, or ownership of ≥$10,000 of the fair market value of the business entity; or if funds received by the person from the business entity exceed 5% of the person’s gross income for the previous year. A relationship is considered to be modest if it is less than significant under the preceding definition. Relationships that exist with no financial benefit are also included for the purpose of transparency. Relationships in this table are modest unless otherwise noted. Names are listed in alphabetical order within each category of review.

According to the ACCF/AHA, a person has a relevant relationship if: a) The relationship or interest relates to the same or similar subject matter, intellectual property or asset, topic, or issue addressed in the document; or b) The company/entity (with whom the relationship exists) makes a drug, drug class, or device addressed in the document; or makes a competing drug or device addressed in the document; or c) The person or a member of the person’s household has a reasonable potential for financial, professional, or other personal gain or loss as a result of the issues/content addressed in the document.

*Significant relationship.
†No financial benefit.
AAFP indicates American Academy of Family Physicians; ACCF, American College of Cardiology Foundation; ACCP, American College of Chest Physicians; AHA, American Heart Association; DSMB, data safety monitoring board; EP, electrophysiology; HRS, Heart Rhythm Society; ISHLT, International Society for Heart and Lung Transplantation; and VA, Veterans Affairs.
Appendix 3. Abbreviations

ACE = angiotensin-converting enzyme
ACS = acute coronary syndrome
AF = atrial fibrillation
ARB = angiotensin-receptor blocker
BMI = body mass index
BNP = B-type natriuretic peptide
CABG = coronary artery bypass graft
CAD = coronary artery disease
CRT = cardiac resynchronization therapy
DCM = dilated cardiomyopathy
ECG = electrocardiogram
EF = ejection fraction
GDMT = guideline-directed medical therapy
HbA1c = hemoglobin A1c
HF = heart failure
HFpEF = heart failure with preserved ejection fraction
HFrEF = heart failure with reduced ejection fraction
HRQOL = health-related quality of life
ICD = implantable cardioverter-defibrillator
LBBB = left bundle-branch block
LV = left ventricular
LVEF = left ventricular ejection fraction
MCS = mechanical circulatory support
MI = myocardial infarction
NSAIDs = nonsteroidal anti-inflammatory drugs
NT-proBNP = N-terminal pro-B-type natriuretic peptide
NYHA = New York Heart Association
PUFA = polyunsaturated fatty acids
RCT = randomized controlled trial
SCD = sudden cardiac death
VAD = ventricular assist device

Measure changes in diastolic function and assess the relationship between diastolic abnormalities and HF risk

Random sample from Olmsted County MN in 1997; age ≥45; participating in baseline and follow up assessments

Diastolic function grade; incident HF

Multivariable survival analysis

Limited to Olmsted County, MN; limited to those following up for 2nd examination

In 4 y between baseline and follow-up, prevalence of diastolic dysfunction increased from 23.8% to 39.2%. Diastolic dysfunction associated with incident HF (HR:1.81)

Data Supplement 4. Health-Related Quality of Life and Functional Capacity (Section 4.4)
Improvement in HRQoL after hospitalization predicts event-free survival in pts with advanced HF. Moser et al 2009. 19879462 (19)

To determine the frequency, durability, and prognostic significance of improved HRQoL after hospitalization for decompensated HF.

Secondary analysis of data from the ESCAPE trial

Hospitalized for NYHA class IV, at least 1 sign of fluid overload EF <30% history of prior HF hospitalization or chronic high maintenance diuretic doses survived to discharge from index admission

Significant comorbid condition that could shorten life (e.g. cancer), pulmonary artery catheter, mechanical circulatory or ventilatory support, IV milrinone within 48 h, dobutamine/ dopamine within 24 h, listed for CTX

Improvement in HRQoL after hospitalization predicts event-free survival in pts with advanced HF. Moser et al 2009. 19879462 (19)

To determine the frequency, durability, and prognostic significance of improved HRQoL after hospitalization for decompensated HF.

Secondary analysis of data from the ESCAPE trial

Hospitalized for NYHA class IV, at least 1 sign of fluid overload EF <30% history of prior HF hospitalization or chronic high maintenance diuretic doses survived to discharge from index admission

Significant comorbid condition that could shorten life (e.g. cancer), pulmonary artery catheter, mechanical circulatory or ventilatory support, IV milrinone within 48 h, dobutamine/ dopamine within 24 h, listed for CTX

HRQoL measured with the MLHFQ

Event-free survival

At baseline HRQoL was severely impaired but improved on average at 1 mo (74.2 ± 17.4 vs 56.7 ± 22.7) and improved most at 6 mo. HRQOL worsened in 51 (16.3%) pts and remained the same in 49 (15.7%). OR: 3.3; p<.009

The only characteristic that distinguished among these groups was whether or not the pt was too ill to perform the 6-min walk. There was a group by time interaction; the degree of improvement across time differed between pts who survived without an event and those who died or were rehospitalized by 6 mo. Pts with events between 1 and 6 mo did not experience as much improvement in HRQoL. A decrease in MLHFQ of >5 points predicted better event-free survival. (p<.0001 group time interaction)

Secondary analysis of data from the ESCAPE trial

HRQoL measured with the MLHFQ

Event-free survival

At baseline HRQoL was severely impaired but improved on average at 1 mo (74.2 ± 17.4 vs 56.7 ± 22.7) and improved most at 6 mo. HRQOL worsened in 51 (16.3%) pts and remained the same in 49 (15.7%). OR: 3.3; p<.009

The only characteristic that distinguished among these groups was whether or not the pt was too ill to perform the 6-min walk. There was a group by time interaction; the degree of improvement across time differed between pts who survived without an event and those who died or were rehospitalized by 6 mo. Pts with events between 1 and 6 mo did not experience as much improvement in HRQoL. A decrease in MLHFQ of >5 points predicted better event-free survival. (p<.0001 group time interaction)

Potential for survivor bias.

Self-reported HRQoL. Relatively short follow-up period of 6 mo.

In pts hospitalized with severe HF decompensation, HRQoL is seriously impaired but improves substantially within 1 mo for most pts and remains improved for 6 mo. Pts for whom HRQoL does not improve by 1 mo after hospital admission merit specific attention both to improve HRQoL and to address high risk for poor event-free survival

QoL and depressive symptoms in the elderly; a comparison between pts with HF and age and gender matched community controls. Lesman-Leegte et al, 2009. 19181289 (20)

To examine whether there are differences in QoL and depressive symptoms between HF pts and an age and gender matched group of community-dwelling elderly and determine how chronic comorbid conditions qualify the answer.

Secondary analysis of COACH trial data plus enrollment of a community sample from Netherlands

NYHA II-IV, ≥18 y, structural heart disease.

Community sample randomly selected from population ≥55 y and not living at same address. 45% response rate.

Enrollment in a study requiring additional research visits or invasive intervention within last 6 mo or next 3 mo, terminal disease, active psychiatric diagnosis.

QoL measured with Medical Outcome Study 36-item General Health Survey and Cantril Ladder of Life. Depressive symptoms with CES-D.

Chronic conditions abstracted from chart of pts, self-reported by community sample.

QoL significantly impaired in HF pts compared to matched elderly. Largest differences were in physical functioning and vitality. Role limitations due to physical functioning very low in HF pts. QoL was lower in HF pts with COPD or diabetes. Depressive symptoms higher in HF pts (39% vs 21%) all p<0.001.

Manner in which comorbid conditions were assessed differed between HF pts and controls. List used was not all inclusive.

HFr has a large impact on QoL and depressive symptoms, especially in women with HF. Differences persist, even in the absence of common comorbidities. Results demonstrate the need for studies of representative HF pts with direct comparisons to age- and gender-matched controls.

<th>Ethnic Differences in QoL in Persons With HF. Riegel et al 2008 16226772 (21)</th>
<th>To compare HRQoL in non-Hispanic white, black, and Hispanic adults with HF</th>
<th>Longitudinal comparative study with propensity scoring</th>
<th>1,212</th>
<th>Established diagnosis of chronic HF</th>
<th>Recent MI, USA, cognitive impairment, severe psychiatric problems, homeless, or discharged to an extended care or skilled nursing facility</th>
<th>HRQoL measured with the MLHFQ</th>
<th>N/A</th>
<th>HRQoL improved over time (baseline to 3- and 6-mo) in all groups but most dramatically among Hispanics. Hispanics improved more than whites (p&lt;0.0001). Hispanics improved more than blacks (p=0.004). Secondary analysis of existing data. Hispanic sample was primarily Mexican so results cannot be generalized to all Hispanics. Samples received different treatments at various sites; treatment was controlled in the analysis. Other factors that could explain these differences were not measured. Cultural bias in the data obtained from the MLHFQ is possible. Cultural differences in the interpretation of and response to chronic illness may explain why HRQoL improves more over time in Hispanic pts with HF compared with white and black pts.</th>

<td>To assess the QoL of pts with HF, due to LV dysfunction, taking optimal medical therapy using baseline QoL assessments from the CARE-HF trial, and to evaluate the appropriateness of using the EQ-5D in pts with HF.</td>
<td>RCT</td>
<td>813</td>
<td>NYHA II-IV HF</td>
<td>None specified</td>
<td>QoL Euroqol EQ-5D and MLHFQ</td>
<td>N/A</td>
<td>There is a relationship between the EQ-5D score and gender, on average females enrolled had a worse QoL than male participants. r=-0.08; 95% CI: -0.13 to -0.04; p=0.00004 Mean EQ-5D score for NYHA III pts was higher than for NYHA IV pts (mean difference 0.17) p&lt;0.0001; 95% CI: 0.08-0.26 Association between MLWFH and EQ-5D scores (increasing MLWFH associated with a decrease in EQ-5D) r=-0.00735; 95% CI: (-0.0085 to -0.0076); p&lt;0.0001 HF is shown to have an important impact on all aspects of QoL but particularly on pts mobility and usual activities and leads to significant reductions in comparison with a representative sample of the UK population. Pts assessed in the study are not a random sample of pts with severe HF. CARE-HF is an int'l study but used available normative data from a representative sample of the UK population to evaluate burden of disease. A study comparing UK and Spanish time trade-off values for EQ-5D health states demonstrated that although the general pattern of value assignation was similar, there were differences in values assigned to a number of health states. The impact of HF varies amongst pts but the overall burden of disease appears to be comparable to other chronic conditions such as motor neurone or Parkinson's disease. The EQ-5D appears to be an acceptable valid measure for use in pts with HF although further evidence of the responsiveness of this measure in such pts is required.</td>

<td>N/A</td>
<td>Life prolonging therapies, such as ACE-Is and ARBs improve modestly or only delay the progressive worsening of QoL in HF. Beta blockers do not affect QoL in any way. Therapies that improve QoL (e.g., inotropic agents) do not seem beneficial in relation to survival.</td>
</tr>
</tbody>
</table>
To evaluate whether the use of usual providers and a reorganization of discharge planning and transition care with improved intersector linkages between nurses, could improve QoL and health services utilization for individuals admitted to hospital with HF.

Prospective randomized trial

Admitted to hospital with a diagnosis of CHF. Residing in the regional home care radius. Expected to be discharged with home nursing care English or French speaking. Admitted for more than 24 h to the nursing units.

Cognitively impaired (score ≥8 on Short Portable Mental Status Exam).

HRQoL (MLWHF), symptom distress and function at 6- and 12-wk postdischarge.

The no. of all-cause ED visits, hospital readmissions, and QoL measured with a generic measure, Medical Outcome Study Short Form.

The overall MLHFQ score was better among the Transitional Care pts than the usual care pts:
- At 6 wk after hospital discharge (p=0.002)
- At 12 wk after hospital discharge (p=0.001)

The MLHFQ's Physical Dimension subscale score was better among the Transitional Care pts than the usual care pts:
- At 6 wk after hospital discharge (p=0.01)
- At 12 wk after hospital discharge (p=0.001)

The MLHFQ's Emotional Dimension subscale score was better among the Transitional Care pts than the usual care pts:
- At 6 wk after hospital discharge (p=0.008)
- 46% of the Usual Care group visited the ED compared with 29% in the Transitional Care group (p=0.03)
- At 12 wk postdischarge, 31% of the Usual Care pts had been readmitted compared with 23% of the Transitional Care pts (p=0.26). Conducted the trial in a naturalistic manner in the usual setting of care with usual providers. Possibility of contamination with the hospital nurses providing usual care. Pts may have inadvertently alerted the research coordinators of their assignment to usual care or transitional care. With multiple interventions it’s not easy to assess neither the relative contribution of each component nor the synergistic effect of the sum of the parts. Transitional Care has an important role to play in altering the course of pts hospitalized with HF. Our results suggest that with modest adjustments to usual discharge and transition from hospital-to-home, pts with CHF can experience improved QoL, and decreased use of ED, for 3 mo after hospitalization. This approach will provide the needed adjunct to current management of HF.

Evaluate the prognosis of viable pts with and without improvement of LVEF after coronary revascularisation.

Observational

90; group 1: viable pts with LVEF improvement (n=27); group 2, viable pts without LVEF improvement (n=15), group 3, non-viable pts (n=48)

Pts were already scheduled for coronary revascularization according to clinical criteria of reduced LVEF (40%), symptoms of HF and/or angina, presence/absence of ischemia and presence of critical coronary disease at angiography. Only pts who had undergone coronary revascularisation alone were included in the study.

Pts who had undergone mitral valvuloplasty or aneurismectomy in association with revascularisation were excluded.

Cardiac events were evaluated during a 4-y follow-up (cardiac death, new MI, admission to hospital for HF)

Cardiac event rate was low (4%) in group 1, intermediate (21%) in group 2 and high (33%) in group 3. After revascularization, the mean (SD) LVEF improved from 32 (9)% to 42 (10)% in group 1, but did not change significantly in group 2 and in group 3, p<0.001 by ANOVA.

HF symptoms improved in both groups 1 (mean (SD) NYHA class from 3.1 (0.9) to 1.7 (0.7)) and 2 (from 3.2 (0.7)-1.7 (0.9)), but not in group 3 (from 2.8 (1.0)-2.7 (0.5)), p=0.001 by ANOVA.

The difference in event rate was not statistically significant between groups 1 and 2 - small number of pts - but it was significant between the 3 groups using Kaplan–Meier p=0.01.

Kevin C Allman 2002

Examines late survival with revascularization vs medical therapy after myocardial viability testing in pts with severe CAD and LV dysfunction

Meta-analysis of observational studies

3,088 (viability demonstrated in 42%)

Pts with CAD and LV dysfunction who were tested for myocardial viability with cardiac imaging procedures from 24 viability studies reporting pt survival using thallium perfusion imaging, F-18 fluorodeoxyglucose metabolic imaging or dobutamine ECHO.

Those not reporting deaths or where deaths could not be apportioned to pts with vs without viability were excluded.

Annual mortality rates, pts followed for 25±10 mo.

For pts with defined myocardial viability, annual mortality rate was 16% in medically treated pts but only 3.2% in revascularized pts (χ² =147, p<0.0001). This represents a 79.6% relative reduction in risk of death for revascularized pts. For pts without viability, annual mortality was not significantly different by treatment method: 7.7% with revascularization vs 6.2% for medical therapy (p=NS).

The individual studies are observational, nonrandomized, unblinded and subject to publication and other biases. In this metaanalysis, viability could only be interpreted as “present” or “absent” based on individual studies’ definitions.

Beanlands RS. 2002

Whether the extent of viability or scar is important in the amount of recovery of LV function and to develop a model for predicting recovery after revascularization that could be tested in a randomized trial.

Prospective multicenter cohort

82; Complete follow-up was available on 70 pts.

Pts CAD and severe LV dysfunction with EF 35% by any quantitative technique, who were being scheduled for revascularization

Pts with MI within the preceding 6 wk, severe valve disease requiring valve replacement, requirement for aneurysm resection, and inability to obtain informed consent.

Absolute change in EF determined by radionuclide angiograms 3 mo postrevascularization

Amount of scar was a significant independent predictor of LV function recovery after revascularization. Across tertiles of scar scores (I, small: 0% to 16%; II, moderate: 16% to 27.5%; III, large: 27.5% to 47%), the changes in EFs were 9.0±1.9%, 3.7±1.6%, and 1.3±1.5% (p=0.003: I vs. III), respectively.

Pt population in this study included pts who were predominantly men, predominately between 53-71 y of age (1 SD from the mean), had multivessel disease, and had bypassable vessels. Although improvement in LV function has been noted at 3 mo of follow-up in many previous studies, recent data suggest that more recovery may be observed with longer follow-up time.
Paul R. Pagley 1997 9264464 (53)

Hypothesized that pts with poor ventricular function and predominantly viable myocardium have a better outcome after bypass surgery compared with those with less viability.

Retrospective cohort 70 pts with EFs <40% without significant valvular disease who were referred for a first coronary bypass surgery and underwent preoperative quantitative planar 201Tl imaging for viability determination. Prior CABS, coexisting valvular disease and underwent concurrent aortic or MV replacement, or those with SPECT imaging

CV death or cardiac transplantation; median time to follow-up was 1177 d (range, 590 to 1826)

The viability index was significantly related to 3-y survival free of cardiac event (cardiac death or heart transplant) after CV death or cardiac bypass surgery (p=0.011) and was independent of age, EF, and number of diseased coronary vessels. Survival free of cardiac death or transplantation was significantly better in group 1 pts on Kaplan-Meier analysis (p=0.018).

Senior R, 1999 10362184 (54)

To evaluate the effect of revascularization on survival in pts with CHF due to ischemic LV systolic dysfunction based on the presence of myocardial viability

Observational prospective 87 CHF (NYHA class II-IV) for at least 3 mo that was treated medically; LVEF <35%; clinical evidence of CAD Significant valvular disease, unstable angina, MI within three months, sustained ventricular tachycardia or AF

Cardiac deaths were defined as those resulting from acute MI, refractory CHF or occurring suddenly and not being attributed to other known causes after a mean follow-up of 40 ± 17 mo.

Pts with at least 5 segments showing myocardial viability underwent revascularization, mortality was reduced by an average of 93% which was associated with improvement in NYHA class as well as LVEF. Pts with <5 segments showing myocardial viability who underwent revascularization (and thus, showing mostly scar), and those with at least 5 segments demonstrating myocardial viability who were treated medically, had a much higher mortality. (95% CI: 22%-99%)

Kwon DH 2009 19356530 (55)

To determine whether the extent of LV scar, measured with DHE-CMR predicts survival in pts with ischemic cardiomyopathy ICM and severely reduced LVEF.

Observational 349 pts with documented ICM (on the basis of 70% stenosis in at least 1 epicardial coronary vessel on angiography and/or history of MI or coronary revascularization), who were referred for the assessment of myocardial viability with CMR

Pts with standard CMR contraindications including severe claustrophobia, AF, and the presence of pacemakers, defibrillators, or aneurysm clips

All-cause mortality was ascertained by social security death index after a mean of follow-up 2.6 ± 1.2 y (median 2.4 y)

Mean scar percentage and transmurality score were higher in pts with events vs those without (39±22 vs 30±20; p=0.003, and 9.7±5 vs. 7.8±5, p=0.004).

Selection bias of an observational study conducted at a large tertiary referral center. Only the pts with no contraindications to CMR underwent the examination.

Ordovas KG. 2011 22012903 (56)

N/A Review paper N/A N/A N/A N/A

An international multicenter study (54) reported a sensitivity of 99% for detection of acute infarction and 94% for detection of chronic infarction. Delayed enhancement occurs in both acute and chronic (scar) infarctions and in an array of other myocardial processes that cause myocardial necrosis, infiltration, or fibrosis. These include myocarditis, hypertrophic cardiomyopathy, amyloidosis, sarcoidosis, and other myocardial conditions. In several of these diseases, the presence and extent of delayed enhancement has prognostic implications.

Intensive Statin Therapy and the Risk of Hospitalization for HF After an ACS in the PROVE IT-TIMI 22 Study Scirica, Benjamin M JACC 2006 16750703 (92)

Determine whether intensive statin therapy reduces hospitalization for HF in high risk pts (intensive statin therapy simvastatin 80 vs. moderate statin therapy pravastatin 40mg)

| Life-expectancy <2 y: PCI within the prior 6 mo (other than for qualifying event); CABG within 2 mo; planned CABG |
| Hospitalization for HF (time to first HF hospitalization that occurred 30 d or longer after randomization) |
| MI |
| Meta-analysis of 4 large RCTs of statin therapy (TNT, A to Z, IDEAL, PROVE-IT) |
| N=27,546 Reduction in HF hospitalization: OR: 0.73; 95% CI: 0.63-0.84; p<0.001 (x2 for heterogeneity = 2.25, p=0.523) |
| Atorvastatin 80mg associated with reduction in HF hospitalization: 1.6% vs. 3.1%; HR 0.55; 95% CI: 0.35-0.85; p=0.008 when adjusted for history or prior HF HR 0.55; 95% CI: 0.35-0.36; p=0.008 |
| Sub-study of PROVE IT-TIMI 22. Did not exclude those with prior HF (low rates) |

Early Intensive vs a Delayed Conservative Simvastatin Strategy in Pts with ACS. Phase Z of the A to Z Trial. RCT 4,162 STEMI or NSTEMI: total cholesterol ≤250 mg/dL; age 21-80; at least 1 high-risk characteristic (>70, DM, hx of CAD, PVD or Receiving statin therapy, planned CABG, PCI planned within 2 wks of enrollment, ALT level >20% ULN, Cr >2.0mg/dL, Composite: CV death, non-fatal MI, readmission for ACS, stroke Individual components of primary endpoint and revascularization due to documented ischemia, all-cause N/A New onset HF reduced with intensive therapy: 5% vs 3.7%; HR 0.72; 95% CI: 0.53-0.98; p=0.04 Primary endpoint did not achieve significance: 16.7% vs 14.4%; HR 0.89; 95% CI: 0.76-1.04; p=0.14 Development of HF was a secondary endpoint. Did not achieve primary endpoint In pts with ACS, intensive statin therapy reduced new onset HF

In pts with ACS, intensive statin therapy reduced new onset HF Also performed meta-analysis of 4 large statin trials (2 ACS, 1 hx of MI, 1 clinically evident CHD) demonstrating benefit of intensive statin therapy in preventing HF hospitalization
Data Supplement 13. Stage C: Factors Associated With Outcomes, All Patients (Section 7.3)

Effect of discharge instructions on readmission of hospitalized pts with HF: do all of the joint commission on accreditation of healthcare organizations HF core measures reflect better care? VanSuch, M. 2006 17142589 (95)

<p>| Study Design | N | Age &gt;18 y, principal diagnosis of HF, hypertensive heart disease with HF, or hypertensive heart and renal disease with HF discharged to home, home care or home care with IV treatment | Pts discharged to skilled nursing facilities or other acute-care hospitals. | Time to: death and readmission for HF or readmission for any cause | N/A | 68% of pts received all instructions, and 6% received no instructions. Pts with all instructions (compared to those who missed at least one type of instruction) were significantly less likely to be readmitted for any cause or HF (p=0.003) Documentation of discharge instructions was correlated with reduced readmission rates. No association between documentation of discharge and instructions and mortality. Discharge instructions given but not documented. Discharge instructions could be a surrogate indicator for another intervention such as higher quality nursing care. Pt factor could have influenced confounding results. Generalizability limited. No active follow-up. Not all quality of care outcomes were assessed. Documentation of discharge information and pt education appears to be associated with reductions in both mortality and readmissions. |

Frequent non-cardiac comorbidities in pts with chronic HF. Dahlstrom, Ulf. 2005

To discuss in more detail the impact of co-existing HTN, DM, COPD in pts with HF.

Review 37 studies None specified None specified N/A N/A

About 50% of pts with untreated HTN will develop HF. Pressure overload leads to the development of LV hypertrophy and diastolic dysfunction.

DM occurs in about 20–30% of pts with HF.

COPD occurs in approximately 20–30% of HF pts.

Anemia occurs in 20–30% of HF pts and is associated with functional impairment and increased mortality and morbidity. Combined treatment with erythropoietin and intravenous iron has shown beneficial effects on clinical symptoms and morbidity.

No limitations addressed.

This review of the literature clearly demonstrates that noncardiac comorbidities are common in pts with HF and that it is important to recognize these conditions and take them into consideration when selecting treatment for these pts. Appropriate treatment of the HF as well as the concomitant diseases will improve the prognosis of these pts.

ACEI indicates angiotensin-converting-enzyme inhibitor; AF, atrial fibrillation; CHF, congestive heart failure; COACH, Community Outreach and Cardiovascular Health; DM, diabetes mellitus; DMP, disease management program; ECHO, echocardiogram; ED, emergency department; EF, ejection fraction; HF, heart failure; HTN, hypertension; IV, intravenous; LVEF, left ventricular ejection fraction; MI, myocardial infarction; N/A, not applicable; NS, not significant; NYHA, New York Heart Association; PCI, percutaneous coronary intervention; pts, patients; QoL, quality of life; RCT, randomized control trial; REHMADE, Repetitive Education at Six-Month Intervals and Monitoring for Adherence in Heart Failure; UMHFP, University of Michigan Heart Failure Program

</thead>
<tbody>
<tr>
<td>To measure the associations among prescription copayment, drug adherence and subsequent health outcomes in pts with HF</td>
<td>Retrospective Cohort Study 5,259 receiving ACE inhibitor 5,144 receiving Beta Blockers 2,373 receiving both</td>
</tr>
<tr>
<td>Receiving 1 dispensing of ACEI, receiving 1 dispensing of beta blockers, had switched ACEI, had switched beta blockers, MPR &lt;20% or &gt;120%, had conflicting data in their dispensing records</td>
<td>Total cost of health care and hospitalization for HF MPR: proportion of d a pt was exposed to a drug while receiving a regimen N/A</td>
</tr>
<tr>
<td>For pts taking ACEI, a $10 increase in copayment was associated with a 2.6% decrease in MPR (95% CI: 2.0 - 3.1%)</td>
<td>For pts taking beta blockers, a $10 increase in copayment was associated with a 1.8% decrease in MPR (95% CI: 1.4 - 2.2%)</td>
</tr>
<tr>
<td>This change in adherence was associated with: a predicted 0.8% decrease in medical costs (95% CI: -4.2 - 2.5%) a predicted 6.1% increase in the risk of hospitalization for chronic HF (95% CI: 0.5 - 12%)</td>
<td>This change in adherence was associated with: a predicted 2.8% decrease in medical costs (95% CI: -5.9 - 0.1%), a predicted 8.7% increase in the risk of hospitalization for chronic HF (95% CI: 3.8 - 13.8%)</td>
</tr>
<tr>
<td>Using prescription dispensing data to assess drug adherence eliminates pts to whom a drug is dispensed only once so may have contributed to high adherence observed. Dispensing data does not capture actual usage. ACEI more expensive than beta blockers resulting in higher copayment. Total medical costs might have been insensitive to specific changes in adherence to HF therapies.</td>
<td>Among pts with HF, higher drug copayments were associated with poorer adherence, although the magnitude of change was small and did not affect total health care costs. It was sufficient to increase risk of hospitalization for HF though.</td>
</tr>
</tbody>
</table>

 eligible and disabled, those with CAD or DM, those with HF related hospitalization (p<0.01).

Adherence lower among those with larger proportions of claims for generic HF drugs, higher CDPS risk scores and those with non-HF-related hospitalizations (p<0.01).
<p>| Associations between outpatient HF process-of-care measures and mortality. Fonarow, G. 2011 | To examine the relationships between adherence to several current and emerging outpatient HF process measures and clinical outcomes. | Longitudinal/Registry 15,177 | Clinical diagnosis of HF or post-MI, LVEF &lt;35%, ≥2 office visits with a cardiologist in the last 2 y | Noncardiovascular medical condition associated with an estimated survival of ≤1 y, received cardiac transplantation | Process-of-care HF measures: ACE inhibitor or ARB use, beta blocker use, aldosterone antagonist use, anticoagulant therapy for AF or flutter, CRT with defibrillator or pacemaker, ICD, and HF education for eligible pts. | Each 10% improvement in composite care was associated with a 13% lower odds of 24-mo mortality (p &lt;0.0001; 95% CI: 0.84-0.90) | All process measures, except aldosterone antagonist use, were each independently associated with improved 24-mo survival (p &lt;0.01 for all except aldosterone antagonist use). | Errors and omissions in the medical chart review process could have occurred. NYHA functional status was not quantified in many of the records, and was instead based on qualitative description. This study analyzed medications prescribed rather than actual pt adherence. Follow-up on vital status was not achieved for all pts. Race/ethnicity, socioeconomic status or pt adherence may be confounding variables. Findings may not apply to practices that differ from the IMPROVE HF outpatient cardiology practices in this setting. | These data demonstrate that adherence to HF process measures for ACEi/ARB, beta blocker, anticoagulation for AF, and HF education is significantly associated with survival in outpts with HF. These HF measures may be useful for assessing and improving HF care. |</p>

<tr>
<td>Pharmacist intervention to improve medication adherence in HF. Murray, M. 2007 10030506 (117)</td>
<td>RCT 314</td>
<td>Age ≥50 y, confirmed diagnosis of HF, regularly used at least 1 CV medication for HF, not using or not planning to use a medication container adherence aid, access to a working telephone, and adequate hearing</td>
<td>Dementia</td>
<td>Medication adherence (tracked by using electronic monitors) and clinical exacerbations that required visits to the ED or hospitalization.</td>
<td>Health-related QoL, satisfaction with pharmacy services, and total direct health care costs.</td>
<td>Medication adherence greater in the intervention group 78.8% vs. 67.9% usual care group (95% CI: 5.0-16.7). At 3 mo, adherence decreased 70.6% in intervention and 66.7 in usual care (95% CI: -5.9-6.5). Medications were taken on schedule 47.2% in the usual care and 53.1% in the intervention group (95% CI: 0.4-11.5). At the end of intervention, taking of medication on schedule decreased 48.9% for usual care and 48.6% in intervention (95% CI: -5.9-6.5). ED visits and hospital admissions were 19.4% less in the intervention group (95% CI: 0.73-0.93). Annual direct health care costs were lower in the intervention group (95% CI: $-7603-$1338). Pts were not permitted to use medication container adherence aids. Intervention involved 1 pharmacist and a single study site that served a large, indigent, inner-city population of pts. Because the intervention had several components, results could not be attributed to a single component. A pharmacist intervention for outpts with HF can improve adherence to cardiovascular medications and decrease health care use and costs, but the benefit probably requires constant intervention because the effect dissipates when the intervention ceases.</td>

Compliance with non-pharmacological recommendations and outcome in HF pts, van der Wal et al, 2010 20436049 (120)
To investigate the association between compliance with non-pharmacological recommendations (diet, fluid restriction, weighing, exercise) and outcome in pts with HF.

Secondary analysis of data from the COACH trial 830
Recently hospitalized for symptomatic HF, confirmed by the cardiologist, with evidence for underlying heart disease.

Invasive intervention within the last 6 mo or planned for the next 3 mo, inclusion in another study with additional visits to provider, or evaluation of CTX.

Composite of death or HF readmission and the number of unfavorable d.

mortality and readmission for HF
Pts non-compliant with ≥1 recommendations had a higher risk of mortality or HF readmission (p=0.01). Non-compliance with exercise was associated with an increased risk for mortality or HF readmission (p=0.01).
Non-compliance with daily weighing was associated with an increased risk of mortality (p=0.02).
Non-compliance (overall) and non-compliance with exercise were associated with a higher risk for HF readmission (p<0.05).
Pts who were overall non-compliant or with weighing and exercise had more unfavourable d than compliant pts (p= 0.01).

Almost half had a first diagnosis of HF during the index hospitalization and then compliance was evaluated 1 mo after discharge, which could have influenced rates. 'Unfavorable d' difficult to evaluate. Self-report instrument used to measure compliance. Socially desirable responses possible.

Nonpharmacologic Measures and Drug Compliance in Pts with HF: Data from the EuroHF Survey, Lainscak et al, 2007 17378994 (121)
To describe the recall of and adherence to nonpharmacologic advice of pts enrolled in the European HF Survey

Descriptive survey of pts from 115 hospitals from 24 European countries 2,331
Clinical diagnosis of HF

Self-reported adherence to nonpharmacologic advice

After hospitalization for HF, pts recalled receiving 4.1 ± 2.7 items of advice with some regional differences. Recall of dietary advice was higher (63%) than for influenza vaccination (36%) and avoidance of NSAIDS (17%). Among those who recalled the advice, many did not follow it completely (cholesterol and fat intake 61%; dietary salt 63%; influenza vaccination 75%; avoidance of NSAIDS 80%). A few indicated they ignored the advice completely. Pts who recalled >4 items versus <4 items were younger and more often received ACE-I (71% vs 62%), beta blockers (51% vs 38%), and spironolactone (25% vs 21%).

Younger pts who were more mobile and had greater social support were more likely to attend interview. Possible response bias.
Younger age and prescription of appropriate pharmacologic treatment are associated with higher rates of recall and implementation.

ACEI indicates angiotensin-converting-enzyme inhibitor; AE, adverse event; AF, atrial fibrillation; ARB, angiotensin receptor blocker; CAD, coronary artery disease; CDPS, Chronic illness and disability payment system; CHF, congestive heart failure; COACH, Community Outreach and Cardiovascular Health; CTX, chest x-ray; CRT, Cardiac resynchronization therapy; CV, cardiovascular; DM, diabetes mellitus; ED, emergency department; EDS, excessive daytime sleepiness; EF, ejection fraction; GWTG-HF, Get with the Guidelines-Heart Failure; HF, heart failure; ICD, implantable cardioverter-defibrillator; IMPROVE-HF, The Registry to Improve the Use of Evidence-Based Heart Failure Therapies in the Outpatient Setting; LOS, length of stay; LVEF, left ventricular ejection fraction.

<td>Continuous positive airway pressure for central sleep apnea and HF (CANPAP). Bradley, T.D. et al. 2005</td>
<td>To test the hypothesis that long-term treatment of CSA with CPAP in HF pts receiving optimal medical therapy reduces the combined rates of death and heart transplant.</td>
<td>11 center RCT</td>
<td>258</td>
<td>18-79 y, NYHA II-IV, HF due to ischemia, HTN, or idiopathic DCM, stable condition, optimal medical therapy for 1+ mo, LVEF &lt;40%, CSA with ≥15 apnea-hypopnea index (AHI) and &gt;50% of AHI had to be central.</td>
<td>Pregnancy, MI, USA, cardiac surgery within prior 3 mo, OSA</td>
<td>Death and heart transplantation</td>
<td>Hospitalizations, EF, exercise capacity, QoL, neurohormones</td>
<td>No difference between control (n=130) and CPAP (n=128) groups in number of hospitalizations, QoL, ANP levels. No difference in overall event rates (p=0.54).</td>
</tr>
<tr>
<td>Suppression CSA by CPAP and transplant-free survival in HF. Arzt, M. 2007</td>
<td>To investigate whether suppression of CSA below threshold by CPAP would improve LVEF and heart transplant-free survival.</td>
<td>Post-hoc analysis of a randomized trial.</td>
<td>210</td>
<td>Age 18 to 79 y, NYHA II-IV HF due to ischemic, hypertensive, or idiopathic DCM, stabilized with optimal medical therapy for at least 1 month LVEF &lt;40%, Central sleep apnea</td>
<td>Pregnancy, MI, Unstable angina, cardiac surgery within 3 mo of enrollment, OSA</td>
<td>Combined rate of all-cause mortality or heart transplantation</td>
<td>Apnea-hypopnea index (AHI) mean nocturnal SaO2, and LVEF</td>
<td>Despite similar CPAP pressure and hours of use in the 2 groups, CPAP-CSA– suppressed subjects, compared to controls, experienced: A greater increase in LVEF at 3 mo (p=0.001)</td>
</tr>
</tbody>
</table>

These results suggest that in HF pts, CPAP may improve both LVEF and heart transplant-free survival if CSA is suppressed soon after it begins.

<td>Systematic review with meta-analysis of randomized trials</td>
<td>241 pts from 8 trials</td>
<td>Adults with chronic HF Diagnosis based on clinical signs or LVEF &lt;40%</td>
<td>None specified</td>
</tr>
</tbody>
</table>

Exercise training conferred modest but statistically significant improvements in self-reported health status compared with usual care without training. Improvements occurred early and persisted over time.

<tr>
<td>A randomized trial of the addition of home-based exercise to specialist HF nurse care: the Birmingham Rehabilitation Uptake Maximization study for pts with CHF (BRUM-CHF) study. Jolly, Kate. 2009</td>
<td>RCT</td>
<td>169</td>
<td>LVEF ≤40% on ECHO; had a severity of at least NYHA II in the previous 24 mo; clinically stable for 4 wk; in receipt of optimal medical treatment and in the care of a specialist HF nurse team from 2 acute hospital trusts and 1 primary care trust in the West-Midlands region, UK; not considered high-risk for a home-based exercise program.</td>
<td>NYHA IV MI; revascularization within the past 4 mo; hypotension; UA; ventricular or symptomatic arrhythmias; obstructive aortic valvular disease; COPD; hypertrophic obstructive cardiomyopathy; severe musculoskeletal problems preventing exercise; case-note reported dementia; current severe psychiatric disorder</td>
<td>Disease-specific QoL measured by the MLHFQ</td>
<td>No between-group difference in the disease-specific QoL MLHFQ at 6 mo (95% CI: -7.87-2.80) and at 12 mo (95% CI: -5.87-4.76). The only secondary outcomes significant for exercise group: Higher generic QoL scores at 6 mo (95% CI: 0.04-0.18); Lower hospital anxiety and depression scale score at 12 mo (95% CI: -2.00 to -0.14). At 6 mo, the control group showed deterioration in physical activity, exercise capacity and generic QoL.</td>
</tr>
<tr>
<td>Exercise training in older pts with HF and preserved EF. Kitzman, Dalane. 2010</td>
<td>RCT</td>
<td>53</td>
<td>Stable with no medication changes for &gt;6 wk; HFpEF defined as history, symptoms and signs of HF Preserved LVEF (&gt;50%); no evidence of significant coronary, valvular or pulmonary disease or any other medical condition that could mimic HF symptoms.</td>
<td>Contraindication to exercise testing or training; unable to perform a valid baseline exercise test; currently exercising regularly; had known cancer; significant renal dysfunction; substance abuse; uncontrolled diabetes; dementia; History of noncompliance; any other disorder that would preclude participation in the intervention and follow-up.</td>
<td>Peak exercise oxygen uptake</td>
<td>Peak exercise oxygen uptake increased significantly in the exercise treatment group compared to the control group (p= 0.0002). There were significant improvements in peak power output, exercise time, 6-minute walk distance, and ventilatory anaerobic threshold (all p&lt; 0.002). There was improvement in the physical quality of life score (but not in the total score) (p= 0.03).</td>
</tr>
</tbody>
</table>

This study failed to demonstrate a benefit from the addition of a home-based exercise program in a community-based HF population. Further evidence is needed to assess the suitability of home-based exercise programs in this population.
| Effects of exercise training in pts with HF: the exercise rehabilitation trial (EXERT). McKelvie, Robert. 2002 | 181 | Documented clinical signs and symptoms of HF LVEF <40%, NYHA I-III, 6MWT distance <500 meters | Inability to attend regular exercise training sessions; exercise testing limited by angina or leg claudication; abnormal blood pressure response to exercise testing; cerebrovascular or musculoskeletal disease preventing exercise testing or training; respiratory limitation; poorly controlled cardiac arrhythmias; any noncardiac condition affecting regular exercise training or decreasing survival. | 6MWT | Peak oxygen uptake, dynamic muscle strength, QoL, and cardiac function | Significant increase in 6-min walk distance at 3 and 12 mo (p= 0.026) but no between-group differences (p= 0.081). Incremental peak oxygen uptake increased in the exercise group compared with control group: At 3 mo: (p=0.014); At 12 mo: (p=0.014) At 3 mo, compared with the control group, increases were seen in exercise group for: Arm Curl and Knee Extension: (p=0.014) No significant changes observed in cardiac function or QoL. | Exercise training improves peak oxygen uptake and strength during supervised training. Over the final 9 mo of the study, there was little further improvement, suggesting that some supervision is required for these pts. There were no adverse effects on cardiac function or clinical events. |
To evaluate the effect of a combined endurance and muscle strength training program on clinical performance data and health-related psychosocial factors in women and men.

Non-randomized study of men vs. women.

Stable chronic HF; LVEF <45%; Peak VO2 <20 ml/min/kg; capable of answering questions on HRQoL and psychological well-being.

Severe pulmonary disorders; neurological deficits; cognitive disorders and physical disabilities which prevented pts from participating in a training program.

LVEF, cardiopulmonary performance, QoL

N/A

Women had a diagnosis of non-IHD and valvular heart disease more commonly than men.

LVEF increased:
Female: p<0.001
Male: p<0.001

LVEDV decreased:
Female: p<0.05
Male: p<0.05

LVESV:
Female: p<0.001
Male: p<0.001

Peak VO2:
Female: p NS
Male: p<0.001

Wattmax (W):
Female: p<0.001
Male: p<0.001

6MWT (m):
Female: p<0.001
Male: p<0.001

Muscle strength training:
Female: p<0.001
Male: p<0.001

Physical Health:
Female: p<0.001
Male: p<0.001

Mental Health:
Female: p<0.01
Male: p<0.05

The results of our study confirm the feasibility of a combined endurance and resistance program, especially for women. Our findings show a considerably reduced cardiopulmonary performance, negatively affecting physical health. In contrast, no essential restrictions were reported by our groups regarding mental health. This underlines the importance of a physical training program and its continuation at home following the hospital stay in order to influence performance data favorably.

<td>The effects of physical training on workload, upper leg muscle function and muscle areas in pts with chronic HF. Senden, Jeff. 2005 15823638 (141)</td>
<td>RCT</td>
<td>77</td>
<td>Chronic HF for at least 6 mo, NYHA II-III, clinically stable for at least 3 mo, received optimal medical therapy, physically able to visit the outpatient clinic, LVEF &lt;35%</td>
<td>Interfering disease such as COPD, fasting glucose &lt;7.0 mmol/L (DM), neuromuscular disorders, HTN</td>
<td>LVEF, body composition, daily physical activity, exercise performance, upper leg muscle area and isokinetic leg muscle variables.</td>
<td>N/A Workload and peak oxygen consumption decreased in the control group and increased in the training group (p&lt;0.05). Hamstrings area decreased in the control group and did not change in the training group (p&lt;0.05). Upper leg muscle function improved in the training group and did not change in the control group (p&lt;0.05). At baseline and after intervention nearly 60% of the variance in maximal workload was explained by upper leg muscle function and quadriceps muscle area. In chronic HF pts, home-based training in conjunction with a supervised strength and endurance training program is safe, feasible and effective and does not require complex training equipment. Physical training prevented loss of hamstrings muscle mass and improved exercise performance by enhancing muscle strength and endurance.</td>
<td></td>
</tr>
<tr>
<td>Antiremodeling effect of long-term exercise training in pts with stable chronic HF. Giannuzzi, Pantaleo. 2003 12860904 (127)</td>
<td>RCT</td>
<td>90</td>
<td>HF secondary to idiopathic DCM, IHD or valvular disease, LVEF &lt;35% by ECHO, clinical stability for at least 3 mo under optimized therapy, NYHA II-III, peak oxygen uptake (VO2) &lt;20mL/kg/min at ergospirometry, echocardiographic images of adequate quality for quantitative analysis</td>
<td>Any systemic disease limiting exercise, hypertrophic cardiomyopathy, valvular disease requiring surgery, angina pectoris, sustained ventricular arrhythmias, severe HTN, excess variability &gt;10% at baseline cardiopulmonary exercise test</td>
<td>Cardiopulmonary exercise testing, 6MWT, ECHO, and QoL.</td>
<td>N/A Differences from baseline to 6 mo improved in the intervention group for: EF (p&lt;0.001), Work capacity (p&lt;0.001), Peak VO2 (p&lt;0.006), Walking distance (p&lt;0.001), QoL (p&lt;0.01), LV volumes (diminished) (p&lt;0.006), Trend to fewer readmissions for worsening dyspnea (EDV p&lt;0.05 ESV) LV volumes increased in control group (p&lt;0.001 EDV ESV) In stable chronic HF, long-term moderate exercise training has no detrimental effect on LV volumes and function; rather, it attenuates abnormal remodeling. Furthermore, exercise training is safe and effective in improving exercise tolerance and QoL.</td>

| Exercise training reduces circulating adiponectin levels in pts with chronic HF. Van Berendoncks, An. 2010 19656085 (142) | To assess circulating adiponectin concentrations in chronic HF pts, compare with controls, and evaluate the effects of a 4-mo exercise training program. Prospective, non-randomized trial 80 LVEF <30%, NYHA II-III, symptoms had been stable on medical treatment for at least 1 mo prior to inclusion Recent ACS or revascularization, valvular disease requiring surgery, exercise-induced myocardial ischemia or malignant ventricular arrhythmia, acute myocarditis or pericarditis, cerebrovascular or musculoskeletal disease preventing exercise testing or training, acute or chronic infections, allergies, cancer or inflammatory disease, DM. Circulating adiponectin concentrations, exercise capacity, anthropometric data and NT-proBNP levels. N/A At baseline, adiponectin levels were significantly higher in chronic HF pts compared with healthy subjects (p=0.015). At baseline, stratification of pts according to tertiles of NT-proBNP revealed an increase in adiponectin with disease severity (p<0.001). Exercise training significantly reduced circulating adiponectin levels in the trained chronic HF group (compared to sedentary chronic HF group) (p=0.008) Circulating adiponectin concentrations are higher in chronic HF pts compared with healthy subjects and increase with disease severity. Exercise training for 4 mo lowers circulating adiponectin levels. The present findings, together with those from other studies, suggest that dysregulation of the adiponectin pathway contributes to the observed metabolic impairment in chronic HF. Effects of exercise training on cardiac performance, exercise capacity and QoL in pts with chronic HF. Van Tol, Benno. 2006 16713337 (143) | To determine the effect of exercise training in pts with chronic HF on cardiac performance, exercise capacity and HRQoL. Meta-analysis of RCTs 35 trials RCTs included pts with chronic HF in the control and in the intervention group (diagnosis based on clinical findings or LVEF <40%), included at least 1 treatment group receiving exercise training and 1 control group which received standard medical treatment w/o additional exercise training, evaluated outcome measures in terms of cardiac performance, exercise capacity and/or HRQoL, exercise training had to include at least one of the following training modalities: walking, cycling or resistive training of peripheral muscles. Studies in which only respiratory muscles or one isolated muscle group was trained. Cardiac performance, exercise capacity and HRQoL. N/A During maximal exercise, significant summary effect sizes were found for: SBP (p=0.03), Heart rate (p=0.011), Cardiac output (p=0.004), Peak oxygen uptake (p<0.001), Anaerobic threshold (p=0.00), 6MWT (p=0.00). The MLHFQ improved by an average of 9.7 points (p=0.00). Exercise training has clinically important effects on exercise capacity and health-related quality of life, and may have small positive effects on cardiac performance during exercise. 6MWT indicates 6 minute walk test; ACS acute coronary syndrome; AF, atrial fibrillation; CHF, congestive heart failure; COPD, chronic obstructive pulmonary disease; CV, cardiovascular; DCM, dilated cardiomyopathy; DM, diabetes mellitus; ECHO, echocardiography; EF, ejection fraction; EXERT, Exercise Rehabilitation Trial; HF, heart failure; HFrEF, heart failure with reduced ejection fraction; HFpEF, heart failure with preserved ejection fraction; HRQoL, health related quality of life; HTN,

<tr>
<td>Primary end point was treatment success, treatment failure, or no change in the pt's condition. Success defined as pt-reported moderate or marked improvement in dyspnea both 24 and 48 h after administration of the study drug, in the absence of any criterion for failure. Failure defined as the occurrence of any of the following: death or readmission for HF through d 7, worsening symptoms and signs of HF occurring &gt;24 h after the initiation of the study drug requiring intervention by d 7 or discharge (if earlier), or persistent WRF, defined as an increase in the SCr level ≥0.3 mg/dL (26.5 μmol/L) from randomization to d 7, confirmed at d 14, or the initiation of hemofiltration or dialysis during the period from initiation of the study drug through d 7. Pts were classified as having unchanged treatment status if they met neither the criteria for treatment success nor the criteria for treatment failure. Two secondary outcomes were prespecified: death from any cause or rehospitalization for cardiovascular or renal causes through d 60 and the proportion of pts with persistent renal impairment, defined as an increase in the SCr level ≥0.3 mg/dL by d 7, confirmed at d 14; the initiation of hemofiltration or dialysis through d 7; or death by d 7. Rolofylline did not provide a benefit with respect to the primary endpoint (OR: 0.92; 95% CI: 0.78-1.09; p=0.35). Persistent renal impairment developed in 15% of pts in the rolofylline group and in 13.7% of pts in the placebo group (OR: 1.11; 95% CI: 0.85-1.46; p=0.44). By 60 d, death or readmission for cardiovascular or renal causes had occurred in similar proportions of pts assigned to rolofylline, 366 of 1356 pts (Kaplan-Meier estimate, 30.7%; 95% CI: 27.8-33.6) as compared with 195 of 677 pts assigned to placebo (Kaplan-Meier estimate: 31.9%; 95% CI: 27.4-36.4) (HR: 0.98; 95% CI: 0.83-1.17; p=0.86). AE rates were similar overall; however, only pts in the rolofylline group had seizures, a known potential adverse effect of A1-receptor antagonists1.</td>

| Clinical composite endpoint of death, rehospitalization, or ED visit during the 60-d follow-up period: HR with continuous infusion: 1.15; 95% CI: 0.83-1.60; p=0.41, HR with high-dose strategy, 0.83; 95% CI: 0.62-1.16; p=0.28 |

| PROTECT, Massie, 2010 20925544 (145) |  |

Rolofylline did not have a favorable effect with respect to the primary composite end point, nor did it improve renal function or 60-d outcomes. It does not show promise in the treatment of acute HF with renal dysfunction. Post hoc selection of the best of 3 dose groups from the pilot trial with multiple small treatment groups carries the risk that an apparent superiority may be the play of chance and may have resulted in the inability to replicate pilot study findings in this more definitive, larger study. Also, clinical relevance of endpoints has been questioned.
Evaluate the effect of low-dose dopamine and furosemide on diuresis and renal function in pts with acute decompensated HF

| RCT | 60 | Age >18 y; history of HF; deterioration of HF, symptoms of recent onset (<6 h), dyspnea at rest, orthopnea, and paroxysmal nocturnal dyspnea, accompanied by signs of congestion (third heart sound, jugular venous distension, pulmonary rales) on physical examination; levels of serum BNP >400 pg/mL or NT pBNP >1,500 pg/mL; and oxygen saturation <90% on admission. | Acute de novo HF; severe renal failure (admission SCr >215 mmol/L [2.5 mg/dL] or eGFR <30 mL min 1 1.73 m²); admission SBP <90 mm Hg; severe valvular disease; known adverse reactions to furosemide or dopamine; HF secondary to congenital heart disease; a scheduled procedure with a need for IV contrast dye in the present hospitalization; and a scheduled cardiac surgery within 2 mo. | Incidence of WRF during the first 24 h from randomization. 2 definitions were used for WRF: 1) >0.3 mg/dL rise in SCr level from baseline to 24 h; and 2) >20% decrease in eGFR from baseline to 24 h |

Changes in SCr, urea, potassium, and eGFR during the first 24 h from randomization; incidence of WRF over the course of hospitalization; total length of stay; and 60-d mortality or rehospitalization rate (all-cause, cardiovascular, and worsening of HF). | Mean hourly excreted urine volume (272±149mL in high-dose furosemide vs 278±186mL in LDFD plus low-dose dopamine group; p=.965) and changes in dyspnea score (Borg index: 4.4±2.1 in high-dose furosemide group vs 4.7±2.0 in LDFD group; p=.575) during the 8 h of protocol treatment were similar in the two groups. WRF was more frequent in the high-dose furosemide (n=9; 30%) than in the LDFD group (n=2; 6.7%; p=.042). Serum potassium changed from 4.3±0.5 to 3.9±0.4mEq/L at 24 h (p=.003) in the high-dose furosemide group and from 4.4±0.5 to 4.2±0.5mEq/L at 24 hours (p=.07) in the LDFD group. Length of stay and 60-d mortality or rehospitalization rates (all-cause, cardiovascular, and worsening of HF). |

Relatively small study, 2 groups did not receive the same dose of furosemide and did not include a low-dose furosemide only group. | This study shows that LDFD infusions are as effective as high-dose furosemide infusions in terms of clinical and diuretic response in pts hospitalized for acute decompensated HF. Moreover, LDFD infusion was associated with significantly lower rates of WRF than high-dose furosemide, suggesting a renoprotective effect in this pt population.
| **Pilot study of furosemide by continuous infusion vs twice-d bolus injection (Duke), L Allen, 2010 20538132 (147)** | RCT | 41 | Primary diagnosis of acute decompensated HF; evidence of volume overload; could be randomized <24 h from hospital presentation | End-stage renal disease or anticipated need for renal replacement therapy; were not expected to survive hospitalization; pregnant | Change in Scr from admission to hospital d 3 or hospital discharge | Cumulative urine output and other electrolyte changes from admission to hospital d 3 as well as hospital length of stay | None of the outcomes showed a statistically significant difference between bolus and continuous dosing from admission to hospital d 3. Nonsignificant trend toward improvement in the bolus dosing arm. Decreases in serum potassium, serum sodium, and SBP showed nonsignificant trends in favor of continuous infusion | Smaller study | No statistically significant differences noted between bolus and continuous infusion |
|---|---|---|---|---|---|---|---|---|---|---|
| **Pilot study comparing the effectiveness of continuous IV with intermittent IV infusion of furosemide in pt with acute decompensated HF (MUSC), Thomson, 2010 20206891 (148)** | RCT | 56 | Admission diagnosis of acute decompensated HF | Pts who had received >2 doses of IV furosemide before randomization | Net daily urine output | Net daily urine output normalized for amount of furosemide received, total daily urine output normalized for amount of furosemide received, weight loss during the study, need for additional HF therapy, duration of study drug administration, length of hospitalization | Mean urine output in 24 h was 2,098±1,132 mL in pt receiving continuous vs 1,575±1100 mL in the bolus group (p=0.086). Total urine output was 3726±1121 mL/24 h in the continuous group vs 2,955±1,267 mL/24 h in bolus group (p=0.019). Length of hospital stay was 6.9±3.7 d in the continuous group vs 10.3±5.3 d in the bolus group (p=0.006) | Smaller study | LOS shorter and mean urine output greater in the continuous infusion group vs bolus group |
| **ADHERE, Peacock, 2008 18480204 (149)** | Registry | 82,540 | Pts in the ADHERE registry who received IV diuretics during a hospitalization for acute decompensated | Pts receiving vasoactive drugs or dialysis. Those who received multiple types of diuretics. Pts with Scr values >6 mg/dL or hospitalizations with LOS <4 h were excluded from the analysis of change in Scr and dialysis | Increase from baseline to last available Scr > 0.5 mg/dL; decrease in GFR >10 mL/min from baseline to discharge; initiation of dialysis during | Inhospital mortality, ICU admission, ICU LOS >3 d, and hospital LOS >4 d | Both before and after risk and propensity adjustments, an increase in Scr >0.5 mg/dL occurred less frequently in LDD admissions than in HDD admissions (both p<0.0001). The prevalence of a >10 mL/min decrease in GFR from baseline to discharge was | ADHERE registry data were retrospective and observational so should be regarded as hypothesis | Among pts in the ADHERE registry, After covariate and propensity adjustments, the inhospital |
HF. This study analyzed data from the ADHERE registry to look at the impact of diuretic dosing. 62,866 pt receiving <160 mg and 19,674 pts ≥160 mg of furosemide were analyzed.

HF. initiation. Pt with SCR values >6 mg/dL, GFR values >200 mL/min, or hospitalizations with LOS <24 h were excluded from the analysis of change in GFR.

hospitalization. significantly lower in LDD vs HDD admissions (p < 0.001). Significant differences between cohorts present after risk and propensity adjustments. LDD treatment was associated with lower prevalence of prolonged ICU LOS (not significant differences). After covariate and propensity adjustments: in-hospital mortality risk of LDD was significantly lower compared to HDD. AUC for adjusted model was 0.78. Unadjusted mortality OR 0.875; 95% CI: 0.787–0.973; p = 0.01. After adjustment for covariates known to be associated with mortality – age, BUN, SBP, DBP, sodium, creatinine, heart rate and dyspnea at rest – adjusted OR was 0.888; 95% CI: 0.795–0.993; p = 0.0364.

This study was a prospective observational analysis of pts in an advanced HF clinic stratified at baseline by diuretic dose (low dose ≤80 mg, high dose >80 mg furosemide equivalent) to evaluate the effect of high/low (or no) diuretic doses on outcomes.

Pts were excluded if they required renal replacement therapy, had a concurrent noncardiac diagnosis expected to limit life expectancy to less than 1 y, or were unable to participate in repeat clinical assessments.

All pts were followed for 1 y. The primary outcome for the analysis was time to first HF event of HF admission, cardiac transplant, MCS, or death.

Secondary outcomes included individual components of the HF composite and WRF, which was defined as an increase in SCR >0.3 mg/dL from baseline.

Compared with pts taking LDD (113 pts [62%]), pts taking HDD (70 pts [38%]) had more markers of increased cardiovascular risk (older, ischemic cardiomyopathy, DM and HTN) and were more likely to have a history of recent instability (33% vs 4.4% in low dose, p < 0.001). SCR significantly higher in pts receiving HDD vs. LDD (1.4 ± 0.5 mg/dL vs 1.1 ± 0.5 mg/dL, respectively, p < 0.001).

1 y cumulative HF event rates significantly greater in pts taking HDD when to low-dose/no diuretics (HF composite, 29% vs 4.5%, p < 0.01; HF hospitalization, 26% vs 4.5%, p < 0.01; MCS or transplant, 7.1% vs 2.7%, P = .02; death, 2.9% vs 0.9%, p = .01; high vs low dose for all). Among pts taking HDD, those with a history of instability had significantly greater HF event rates during a 1 y period compared with pts with recent initiating.

Secondary outcomes for initiation of IV diuretics was not collected and therefore not considered in analysis. Cohort study high vs. low dose (Brigham and Women's) Mielniczuk, 2008 18514930 (150)

This study was a prospective observational analysis of pts in an advanced HF clinic stratified at baseline by diuretic dose (low dose ≤80 mg, high dose >80 mg furosemide equivalent) to evaluate the effect of high/low (or no) diuretic doses on outcomes.

Pts were excluded if they required renal replacement therapy, had a concurrent noncardiac diagnosis expected to limit life expectancy to less than 1 y, or were unable to participate in repeat clinical assessments.

All pts were followed for 1 y. The primary outcome for the analysis was time to first HF event of HF admission, cardiac transplant, MCS, or death.

Secondary outcomes included individual components of the HF composite and WRF, which was defined as an increase in SCR >0.3 mg/dL from baseline.

Compared with pts taking LDD (113 pts [62%]), pts taking HDD (70 pts [38%]) had more markers of increased cardiovascular risk (older, ischemic cardiomyopathy, DM and HTN) and were more likely to have a history of recent instability (33% vs 4.4% in low dose, p < 0.001). SCR significantly higher in pts receiving HDD vs. LDD (1.4 ± 0.5 mg/dL vs 1.1 ± 0.5 mg/dL, respectively, p < 0.001). 1 y cumulative HF event rates significantly greater in pts taking HDD when to low-dose/no diuretics (HF composite, 29% vs 4.5%, p < 0.01; HF hospitalization, 26% vs 4.5%, p < 0.01; MCS or transplant, 7.1% vs 2.7%, P = .02; death, 2.9% vs 0.9%, p = .01; high vs low dose for all). Among pts taking HDD, those with a history of instability had significantly greater HF event rates during a 1 y period compared with pts with recent initiating.

Clinical reasons for initiation of IV diuretics was not collected and therefore not considered in analysis. Mortality risk of pts who received LDD was significantly lower compared to those receiving HDD.

</tbody>
</table>

SBP <95 or >160 mm Hg; fever >38°C; acute contrast-induced nephropathy; resistant hypokalemia; ongoing or planned IV therapy with positive inotropic agents, vasopressors, vasodilators with the exception of IV nitrates, or mechanical support (intra-aortic balloon pump, endotracheal intubation, or ventricular assist device); severe pulmonary disease; significant stenotic valvular disease; previous heart transplant or admission for cardiac transplantation; clinical evidence of ACS <2 wk before screening; and acute HF caused by significant arrhythmias; pts at high risk of seizures

The prespecified primary analysis for this pilot phase was a trichotomous classification of pts as "success," "unchanged," or "failure" based on their changes in symptoms and renal function. This pilot phase was not powered to demonstrate statistically significant changes. The major objective was to evaluate the performance of this novel endpoint and refine it on the basis of real-world experience.

Treatment success was defined as an improvement in dyspnea (reported by the pt using a 7-point Likert scale as moderately or markedly better compared with study start) determined at 24 and 48 h after the start of study drug (d 2 and 3) or d of discharge if earlier, as long as the pt did not meet any of the criteria for treatment failure. Treatment failure was defined as death, early HF readmission (occurring Composite of death or all-cause readmission within 60 d)

Pts treated with rololofylline more likely to achieve success, as evidenced by improved dyspnea (62.7% vs 37.2%), and less likely to experience failure (manifested by worsening HF, death, or renal impairment) compared with pts treated with placebo (16.2% vs 28.2%). By comparing rololofylline 30 mg with placebo, the OR estimated from the proportional odds model was 0.51 (95% CI: 0.28–0.94). In the prespecified subgroup of pts with higher natriuretic peptide levels, pretreatment BNP level ≥500, or NT pro-BNP ≥2000 pg/mL, most likely representing more severe acute HF, the OR from the proportional odds model was 0.59 (95% CI: 0.30–1.17). SCr increased in pts receiving placebo and remained stable or tended to decrease in those receiving rololofylline. On d 14 the absolute differences between placebo and rololofylline for change in creatinine increased with increasing rololofylline dose, reflecting the lesser increase in creatinine in rololofylline-treated pt (r = -0.12, p=0.030). Treatment with 30 mg, the dose selected for the pivotal trials, was associated with a trend toward reduced 60-d mortality or readmission for cardiovascular or renal cause (HR: 0.55, 95% CI: 0.28-1.04).

Limited by the study size and number of treatment groups. Study was not powered to quantitatively distinguish between the 3 active doses, although trends emerged suggesting a dose-related preservation of renal function and increase in diuresis, as well as a greater effect on the composite endpoint at the 30 mg dose.

The preservation of renal function associated with rololofylline, a selective renal vasodilator, is the first evidence that an intervention to prevent renal impairment may positively affect acute symptoms and 60-d outcome in pts with acute HF; however results were not confirmed in the phase III trial.
within 7 d of study drug initiation), worsening HF as defined daily by the physician assessment by d 7, or persistent renal impairment as defined above. Unchanged pts were classified as unchanged if neither criteria for success or failure were met.

DIG, Ahmed, 2008
17532064 (152)
The objective of this propensity-matched study was to determine the effect of diuretics on mortality and hospitalizations in HF pts ≥65 y.

Registry 7,788 Pts who were at ≥21 y of age were eligible for the main trial if they had HF, a LVEF ≤45%, were in normal sinus rhythm, and did not meet any of 20 easily determined, not overly restrictive exclusion criteria.

Age <21 yrs; baseline EF not available; MI, cardiac surgery or PTCa within 4 wk; unstable or refractory angina <1 month; II-III AV block without pacemaker; AF or flutter; cor pulmonale; constrictive pericarditis; acute myocarditis; hypertrophic cardiomyopathy; complex CHD; tx with IV inotropic agents; K+ < 3.2 mmol/L or >5.5 mmol/L; on heart transplant list; noncardiac cause of HF; Creatinine >3.0 mg/dL or severe liver disease; unlikely to comply. All-cause mortality and all-cause hospitalization during 36.7 mo of median follow-up.

Mortality and hospitalizations due to cardiovascular causes and HF. All-cause mortality occurred in 173 pts not receiving diuretics and 208 pts receiving diuretics respectively during 2,056 and 1,943 person-y of follow-up (HR:1.36; 95% CI:1.08-1.71; p=0.009). All-cause hospitalizations occurred in 413 pts not receiving and 438 pts receiving diuretics respectively during 1,255 and 1,144 person-y of follow-up (HR: 1.18; 95% CI: 0.99-1.39; p=0.063). Diuretic use was associated with significant increased risk of cardiovascular mortality (HR:1.50; 95% CI:1.15-1.96; p=0.003) and HF hospitalization (HR:1.48; 95% CI: 1.13-1.94; p=0.005).

EVEREST, Gheorghiade, 2007
17394438 (153)
To evaluate short-term effects of tolvaptan when added to standard therapy in pts hospitalized with HF.

RCT 2,048 (trial A) and 2,085 (trial B) Age ≥18 y with a history of chronic HF (requiring treatment for a minimum of 30 d before hospitalization) who had been hospitalized primarily for worsening CHF and had a LVEF ≤40% (measured at any point within 1 y of admission). Entry required HF cardiac surgery within 60 d of enrollment, cardiac mechanical support, biventricular pacemaker placement within the last 60 d, comorbid conditions with an expected survival of less than 6 mo, acute MI at the time of hospitalization, hemodynamically significant uncorrected primary cardiac valvular disease, refractory end-stage HF, hemofiltration or dialysis, supine systolic arterial blood pressure of less than 90 mm Hg, SCr concentration >3.5 mg/dL (>309.4 μmol/L), serum potassium concentration > 5.5 mEq/L, and Composite of changes in global clinical status based on a visual analog scale and body weight at d 7 or discharge if earlier.

Dyspnea (d 1), global clinical status (d 7 or discharge), body weight (d 1 and 7 or discharge), and peripheral edema (d 7 or discharge). Rank sum analysis of the composite primary endpoint showed greater improvement with tolvaptan vs placebo (trial A, mean [±SD], 1.06 [0.43] vs 0.99 [0.44]; and trial B, 1.07 [0.42] vs 0.97 [0.43]; both trials p<.001). Mean (±SD) body weight reduction was greater with tolvaptan on d 1 (trial A, 1.71 [1.60] vs 0.99 [1.83] kg; p<.001; and trial B, 1.82 [2.01] vs 0.95 [1.86] kg; p<.001) and day 7 or discharge (trial A, 3.35 [3.27] vs 2.73 [3.34] kg; p<.001; and trial B, 3.77 [3.59] vs 2.79 [3.46] kg; p<.001). Improvements in global clinical status were not different between groups. More pts receiving tolvaptan (984 N/A In pts hospitalized with HF, oral tolvaptan in addition to standard therapy including diuretics improved many, though not all, HF signs and symptoms, without serious AE.

Mortality from worsening HF, and hospitalizations due to all causes and worsening HF

**Mortality from worsening HF, and hospitalizations due to all causes and worsening HF**

Mean survival times for diuretic vs. no-diuretic pts: 47 (95% CI: 46–48) and 50 (95% CI: 49–51) mo.

All-cause mortality was 21% for no-diuretic pts and 29% for diuretic pts (HR: 1.31; 95% CI: 1.11-1.55; p=0.002).

HF hospitalizations occurred in 18% of no-diuretic pts and 29% for diuretic pts (HR: 1.31; 95% CI: 1.11-1.55; p=0.002).

Mortality due to HF occurred in 6% of pts in the no-diuretic group and 9% of those in the diuretic group (HR: 1.36; 95% CI 0.99–1.87; p=0.056).

Compared with 8% deaths among pts never receiving diuretics during the first 24 mo of follow-up, 19% of those who

**Based on non-randomized findings, retrospective. Beta-blockers were not approved for HF during the DIG trial and data on beta-blocker use were not collected**

Chronic diuretic use was associated with increased long-term mortality and hospitalizations in a wide spectrum of ambulatory chronic systolic and diastolic HF pts.
| DIG, Domanski, 2006 | 6,797 | Investigate the associations between death, cardiovascular death, death from worsening HF, SCD, and HF hospitalization among those taking a PSD, NPSD, or no diuretic in the DIG trial. The DIG randomly assigned 6800 pts with HF and LVEF ≤45% to digoxin or placebo in a double-blinded controlled trial. Age <21 y; baseline EF not available; MI, cardiac surgery or PTCA within 4 wk; unstable or refractory angina <1 mo; I-II AV block without pacemaker; AF or flutter; cor pulmonale; constrictive pericarditis; acute myocarditis; hypertrophic cardiomyopathy; amyloid cardiomyopathy; complex CHD; tx with IV inotropic agents; K+ < 3.2 mmol/L or > 5.5 mmol/L; on heart transplant list; noncardiac cause of HF; Creatinine > 3.0 mg/dL or severe liver disease; unlikely to comply. All-cause death, cardiovascular death, death from progressive HF, SCD, and HF hospitalization. N/A. For death from HF or SCD, the incident rates were not significantly different between the pts taking the PSD only versus no-diuretic group (p=0.06, and p=0.7, respectively); for the other 4 events (hosp for HF, death from CVD, death from all causes, hosp or death from HF), the incidence rates were all significantly lower in the no-diuretic group than in the PSD-only group (p=0.01). For all 6 events, the incidence rates for the NPSD only group were significantly higher than the PSD-only group (p=0.02). The incidence rates for the NPSD-only group and both-diuretic groups were comparable and not significantly different with the p-values ranging from 0.07 to 0.6 (date not shown). After multivariate analysis, the risks of all 6 endpoints were increased in pts taking a NPSD, whether or not they were taking a PSD after adjusting for known covariates. There was no significant difference in the risk of any of these events for pts taking only PSD and those taking no diuretics. Compared with not taking diuretic, risk of death (RR: 1.36, 95% CI: 1.17–1.59, p<0.0001), cardiovascular death (RR: 1.38, 95% CI: 1.17–1.63; p=0.0001), progressive HF death (RR: 1.41, 95% CI: 1.06–1.89; p=0.02), SCD (RR: 1.67, 95% CI 1.23–2.27; p=0.01), and HF hospitalization (RR: 1.68, 95% CI: 1.41–2.00). Post-hoc study and doses of diuretics were not available for analysis. Also, did not analyze effects of treatment over time. Beta-blockers were not approved for HF during the DIG trial and data on beta blocker use were not collected. Among pts in the DIG trial, compared with pts not taking any diuretic or taking a PSD, pts taking non-PSD had a higher RR of death. |
This study sought to determine the dose-dependent relation between loop diuretic use and HF prognosis. The study population consisted of 1,354 consecutive pts with advanced systolic HF referred to a single university medical center for HF management and/or transplant evaluation from 1985 to 2004. Pts with LVEF >40%, those with HF due to valvular disease, and those aged <18 y were excluded from the analysis. All-cause mortality was analyzed as a secondary endpoint.

Pts with HF in the highest diuretic dose quartile were found to have significantly impaired survival compared with pts in the lowest quartile. Survival estimates at 1 y were 91%, 88%, 80%, and 69% for quartiles 1, 2, 3, and 4, respectively (p <0.0001). Survival estimates at 2 y were 83%, 81%, 68%, and 53%, respectively (p <0.0001). Death from any cause: HR: 3.4, 95% CI: 2.4-4.7. Death and urgent transplantation: HR 2.7, 95% CI 2.0-3.5. Death from progressive HF: HR: 3.8; 95% CI 2.1-6.8. Sudden death: HR: 3.6; 95% CI: 1.9-6.8. Univariate analysis compared with the lowest quartile, increasing loop diuretic dose quartiles were associated with a progressive increase in mortality (second quartile, HR: 1.2; 95% CI: 0.8-1.7; third quartile, HR: 2.1, 95% CI 1.5-2.9; and fourth quartile, HR: 3.4; 95% CI 2.4-4.7). Diuretic dose quartiles were associated with increased mortality independent of other covariates. After adjustment the highest diuretic quartile remained a significant predictor of increased mortality at 1 y (HR: 4.2; 95% CI: 1.5-11.3) and at 2 y (HR: 4.0; 95% CI 1.9-8.4).

Possible selection bias. Diuretic dose was examined at only a single point in time, without considering changes in doses over time. Baseline characteristics and other HF treatments differed among the diuretic dose quartiles. With adjustment for multiple covariates, larger loop diuretic doses could still be a surrogate for other measured and unmeasured variables that reflect more severe HF. Serum potassium and magnesium level information was unavailable. Propensity matching was not performed. So the relation between this study suggests that in pts with advanced systolic HF, the use of higher doses of loop diuretics is associated with significantly increased all-cause mortality. Although it may appear obvious that pts with HF requiring higher loop diuretic doses to prevent fluid retention and control symptoms might be sicker than pts receiving lower doses, the powerful and independent association with mortality warrants further consideration.

<td>To compare the effects and adverse effects of continuous IV infusion of loop diuretics with those of bolus IV administration among pts with HF class III-IV</td>
<td>Meta-analysis</td>
<td>254 RCTs comparing the efficacy of continuous IV infusion versus bolus IV administration of loop diuretics in HF in a total of 8 RCTs.</td>
<td>(7 studies) urine output, cc/24 h; Electrolyte disturbances (hypokalemia, hypomagnesemia); adverse effects (tinnitus and hearing loss); (single study) duration of hospital stay and cardiac mortality; (2 studies) all cause mortality</td>
<td>N/A</td>
<td>Urine output: the output (as measured in cc/24 h) was noted to be greater in pts given continuous infusion with a WMD of 271 cc/24 h (95%CI: 93.1-449; p&lt;0.01). Electrolyte disturbances were not significantly different in the two treatment groups: RR 1.47; 95%CI: 0.52-4.15; p=0.5. Less adverse effects (tinnitus and hearing loss) were noted with continuous infusion: RR 0.06; 95%CI: 0.01-0.44; p=0.005. Duration of hospital stay was significantly shortened by 3.1 d with continuous infusion WMD -3.1; 95%CI -4.06 to -2.20; p&lt;0.0001; while cardiac mortality was significantly different in the two treatment groups, RR: 0.47; 95% CI: 0.33 to 0.69; p&lt;0.0001. All-cause mortality was significantly different in the two treatment groups, RR: 0.52; 95% CI: 0.38-0.71; p&lt;0.0001. Available data were insufficient to confidently assess the merits of the 2 methods of giving IV diuretics. The existing data did not allow definitive recommendations for clinical practice. Based on small and relatively heterogeneous studies, this review showed greater diuresis and a better safety profile when loop diuretics were given as continuous infusion.</td>

<td>Study sought to determine whether NPSDs in the absence of a PSD may result in progressive HF.</td>
<td>Registry</td>
<td>6,797 Symptomatic and asymptomatic pts with a LVEF fraction &lt;0.36 were randomly assigned to double-blinded treatment with enalapril or placebo. Only drug class was ascertained; specific medications were not recorded.</td>
<td>Rates of hospitalization for HF, death from cardiovascular disease, death from all causes, and either hospitalization or death due to worsening HF</td>
<td>N/A</td>
<td>The risk of hospitalization from worsening HF in those taking a PSD relative to those taking only a non-PSD was 0.74; 95% CI 0.55-0.99; p= 0.047. The RR for cardiovascular death was 0.74; 95% CI 0.59-0.93; p=0.011), for death from all causes 0.73; 95% CI: 0.59-0.90; p=0.004), and for hospitalization for, or death from, HF 0.75; 95% CI: 0.58-0.97; p=0.030). Compared with pts not taking any diuretic, the risk of hospitalization or death due to worsening HF in pts taking this study is retrospective and, therefore, not definitive proof that NPSDs cause progressive HF. Because the diuretic dosage was not available, we cannot draw conclusions about a dose-response This study shows that in pts with moderate or severe LV dysfunction, the use of a PSD is associated with a reduced risk of death or hospitalization due to loop diuretic dose and increased mortality is causative.</td>

© American College of Cardiology Foundation and American Heart Association, Inc. 71
The prognostic importance of diuretic resistance (as evidenced by a high-dose requirement) was retrospectively evaluated in pts with advanced HF who were enrolled in the PRAISE Registry 1,153 LVEF <30% and NYHA functional class IIIb/IV HF despite mandatory background treatment with digoxin, diuretics, and ACE inhibitors. Pts were excluded if their serum potassium level was <3.5 or >5.5 mmol/L and if their SCr level was >3.0 mg/dL (270 >mol/L), and/or if they met other standard exclusion criteria.

### Death or cardiac transplantation

| Non-PSDs alone | RR: 1.31 (95% CI: 1.09-1.57; p=0.0004) | This was not observed in pts taking PSDs with or without a NPSD (RR: 0.99; 95% CI: 0.76-1.30; p=0.95). Relationship. Also, baseline data were used, and diuretic treatment status may have changed over time. Progressive HF, relative to pts taking only a non-PSD. |

The prognostic importance of diuretic resistance (as evidenced by a high-dose requirement) was retrospectively evaluated in pts with advanced HF who were enrolled in the PRAISE Registry 1,153 LVEF <30% and NYHA functional class IIIb/IV HF despite mandatory background treatment with digoxin, diuretics, and ACE inhibitors.

### Pts were excluded if their serum potassium level was <3.5 or >5.5 mmol/L and if their SCr level was >3.0 mg/dL (270 >mol/L), and/or if they met other standard exclusion criteria.

### Death or cardiac transplantation

HDD were independently associated with mortality, sudden death, and pump failure death (aHR: 1.37 (p=0.004), aHR: 1.39 (p=0.042), and aHR: 1.51 (p=0.034), respectively. Use of metolazone was an independent predictor of total mortality (aHR: 1.37; p=0.016) but not of cause-specific mortality. In quartiles of loop diuretic dose, total mortality increased progressively without a clear risk threshold, more than doubling from the lowest-dose group to the highest-dose group (p=.001). Unadjusted mortality rates were 20.7% (n=152), 30.7% (n=313), 36.8% (n=304), and 44.8% (n=84) for increasing dose of furosemide (40 mg, 40-80 mg, 80-120 mg, and 120 mg daily) or bumetanide (1 mg, 1-2 mg, 2-3 mg, and 3 mg daily), respectively. By proportional hazard regression, high diuretic dose was an independent predictor of total mortality (aHR: 1.37; p=0.004), sudden death (aHR: 1.39; p=0.042), and pump failure death (aHR: 1.51; p=0.034).

Retrospective study as pts enrolled in PRAISE were not on beta blockers.

Found that high doses of loop diuretic (>80mg of furosemide or >2mg of bumetanide daily) were independently associated with mortality in pts with advanced HF. When degree of congestion was considered together with its treatment, the associated risks were additive, suggesting that diuretic resistance should be considered an indicator of prognosis in chronic HF. However, retrospective analysis does not establish harm, nor rule out a long-term
This study was designed to evaluate the consequences of UF and standard IV diuretic (furosemide) therapy on GFR and renal plasma flow in pts with acute decompensated HF. 

**RCT 19** Pts hospitalized for acute decompensated HF with an EF <40% and ≥2 signs of hypervolemia based on at least 2 of the following findings: ≥2+ pitting edema of the lower extremities, jugular venous pressure ≥10 cm H2O, pulmonary edema or pleural effusion on chest radiograph consistent with decompensated congestive HF, ascites, paroxysmal nocturnal dyspnea, or ≥2 pillow orthopnea. Pts with ACS, SCR >3.0 mg/dL, SBP ≤ 90 mm Hg, hematocrit >45%, inability to obtain venous access, or clinical instability likely to require IV nitropрусside or IV pressors, history of administration of IV diuretics and/or vasoactive drugs during the present hospitalization (except for a single dose of IV diuretics administered in the ED before hospitalization), use of iodinated radiocontrast material, contraindication to the use of anticoagulation, systemic infection, or hemodialysis were excluded from the substudy.

Urine output, GFR (as measured by iothalamate), and renal plasma flow (as measured by para-aminohippurate) were assessed before fluid removal and after 48 h. N/A 19 pts (59 +/- 16 y, 68% were male) were randomized to receive UF (n= 9) or IV diuretics (n= 10). The change in GFR (-3.4 +/- 7.7 mL/min vs -3.6 +/- 11.5 mL/min; p= .966), renal plasma flow (26.6 +/- 62.7 mL/min vs 16.1 +/- 42.0 mL/min; p= .869), and filtration fraction (-6.9 +/- 13.6 mL/min vs -3.9 +/- 13.6 mL/min; p= .644) after treatment were not significantly different between the UF and furosemide treatment groups. No significant difference in net 48-h fluid removal between the groups (-3211 +/- 2345 mL for UF and -2725 +/- 2330 mL for furosemide, p= .682). UF removed 3666 +/- 2402 mL. Urine output during 48 h was significantly greater in the furosemide group (5786 +/- 2587 mL) compared with the UF group (2286 +/- 915 mL, p< .001).

**Unload UNLOAD substudy** (Maryland), Rogers, 2008 18226766 (160)

To compare the safety and efficacy of venovenous UF and standard IV diuretic therapy for hypervolemic HF pts

**RCT 200** Pts hospitalized with primary diagnosis of acute decompensated congestive HF; evidence of fluid overload as indicated by: pitting edema (2+4) of lower extremities; jugular venous distension; pulmonary edema or pleural effusion; ascites; ACS; creatinine >3.0; SBP <90 mmHg; hematocrit >45%; prior administration of IV vasoactive drugs in the ED; clinical instability requiring pressors during hospitalization; recent use of iodinated contrast material; severe concomitant disease expected to prolong hospitalization; sepsis; on or during a 48-h period, UF did not cause any significant differences in renal hemodynamics compared with the standard treatment of IV diuretics.

Primary efficacy endpoints:
- Weight loss was greater in the UF than in the standard-care group (5.0 ± 3.1 kg vs. 3.1 ± 3.5 kg; p=0.0001)
- Dyspnea scores were similarly improved in the UF and standard-care group at both 8 and 48 h.
- Primary safety endpoints:
  - Changes in SCR were similar in the 2 groups throughout the study and % of pts with rise in SCR >0.3 mg/dL were smaller single center study. Pts receiving UF tended to have worse GFR at baseline. Renal hemodynamic outcomes were measured during acute fluid removal (48 h). Unknown as to when changes in GFR or RPF occur. The present study does not assess any chronic effects of UF or diuresis.

Population not representative of HF pts (better renal function, and excluded pts with hypotension); industry sponsored; While weight loss was greater and rehospitalization at 90 d was lower in the UF arm, data not available on long-term effects on renal function or resource utilization. The pts in trial represented...
| Case-series (Mayo clinic), Liang, 2006 | Present data on UF from a series of pts treated at the Mayo clinic who were generally sicker and had failed at least 1 IV treatment | Case-series | 11 | HF pts admitted to Mayo clinic who have failed at least 1 IV diuresis treatment | Contraindication to UF | Change in creatinine, fluid loss; complications from UF | N/A | 5 pts had significant rise in creatinine, 5 required dialysis, overall 6-mo mortality 55%, bleeding and complications related to positional flow were common. | Small trial; usual care group not very aggressively treated | hemodynamically stable/congested HF pts that respond very well to diuretics and have better outcomes vs. HF population in general. |
| RAPID-CHF, Bart, 2005 | Pilot study which compared a single 8-h UF intervention to usual care in pts admitted with decompensated HF | RCT | 40 | Hospitalized with primary diagnosis of HF; at least 2+ edema of the lower extremities and at least either JVP >10, pulmonary edema or pleural effusion on CXR, pulmonary rales, pulmonary wedge or LVEDP >20, ascites, or pre-sacral edema | Severe stenotic valvular disease; ACS; SBP <90; hematocrt >40% 5. poor peripheral venous access; hemodynamic instability; use of iodinated radioc contrast within 72 h of consent or anticipated use; severe concomitant disease | 24-h weight loss | Total volume removal at 24 and 48 h; global HF and dyspnea assessments; serum electrolytes; and length of hospital stay | No difference in 24-h weight loss (p=0.240), significantly more fluid removal with UF (4,650 mL in UF group vs. 2,838 mL in usual care group, (p=0.001) and improved dyspnea scores (p=0.039) and no change in creatinine. Trend toward greater weight loss at 24 h in the UF group | Small study, pilot | UF group had more fluid removed, with no significant change in creatinine, however no difference in 24 h weight loss. |
| EUPHORIA, Costanzo, 2005 | Compared UF to historical controls in order to determine if use of UF before any IV diuretics in pts with decompensated HF and modest renal dysfunction reestablishes euvo lemic and permits hospital discharge in ≤3 d, without hypotension, a ≥25% increase in SCR or other AEs. | Observational study | 20 | Volume overload; modest degree of renal dysfunction or diuretic resistance (chronic daily PO furosemide ≥80 mg, or torsemide ≥40 mg, or bumetamide ≥ 2mg and SCR ≥1.5 mg/dl), relatively high diuretic requirement at baseline; <12 h since hospitalization, given no vasoactive drugs and <1 dose IV diuretic | Hematocrit >40%, end-stage renal disease requiring dialysis; Hypocholesterolemia; SBP <95 mm Hg; Requirement for IV inotropes; Participation in another research study or previously in this trial | Weight loss; hospital length of stay | Increase in creatinine >25%, hypotension, BNP levels | An average of 8,367 ± 4,232 mL were removed with 2.6 ± 1.2, 8 h UF courses. Of the 19 pts 12 (68%) were discharged in ≤3 d | Small observational study; Single-center series | Concluded that UF decreases length of stay and readmissions. compared the treatment period with the pre-treatment period, rather than with a randomized control cohort. |

paroxysmal nocturnal dyspnea or 2-pillow orthopnea requires renal dialysis; history of cardiac transplant; heparin allergy. unscheduled clinic and ED visits in the wk after inpt treatment similar in both groups at 24 h, 48 h and at discharge Serum potassium <3.5 mEq/l occurred in 1% of the UF group and 12% of diuretics group (p=0.018)

kg in last 6 mo); therapeutic digoxin level (if on digoxin) severe ventricular arrhythmias or an artificial pacemaker peak oxygen consumption (mL/min per kg) increased from 15.5 ± 1 (d -1) to 17.6 ± 0.9 (d 4), to 17.8 ± 0.9 (d 30), to 18.9 ± 1 (d 90) and to 19.1 ± 1 (d 180). Oxygen consumption at anaerobic threshold (mL/min per kg) also increased from 11.6 ± 0.8 (d -1) to 13 ± 0.7 (d 4), to 13.7 ± 0.5 (d 30), to 15.5 ± 0.8 (d 90) and to 15.2 ± 0.8 (d 180). These changes were associated with increased ventilation, tidal volume and dead space/tidal volume ratio at peak exercise. Improvement in exercise performance was associated with a decrease in norepinephrine at rest, a downward shift of norepinephrine kinetics at submaximal exercise and an increase in norepinephrine during orthostatic tilt. None of these changes were recorded in group B.

**Post-MI ACEI Use**
To test the hypothesis that the long-term administration of captopril to survivors of acute MI who had baseline LV dysfunction but did not have overt HF requiring vasodilator therapy would reduce mortality, lessen deterioration in cardiac performance, and improve clinical outcome.

| RCT | Beta-blockers | Ischemic | Alive 3 d after MI; LVEF <40%; >21 y of age, but <80; Killip class I — 60% (60% of the pts did not have even transient pulmonary congestion at baseline/the time of their acute MI; EF 31%; BP 113/70; HR 78; | Failure to undergo randomization within 16 d after the MI; Relative contraindication to the use of an ACEIs or the need for such an agent; SCr > 2.5 mg/dl | Mortality from all causes; Mortality combined with a decrease in the EF of at least 9 units in surviving pts; CV morbidity (development of severe CHF or the recurrence of MI); Combination of CV mortality and morbidity; 2 endpoints of severe HF (treatment failure): 1st, development of overt HF necessitating treatment with ACEI and 2nd, hospitalization to treat CHD. | 3.5 y | Mortality from all causes was significantly reduced in the captopril group (228 deaths, or 20%) as c/w the placebo group (275 deaths, or 25%); the RR: 19% (95% CI, 3-32%; p= 0.019). RR: 21% (95% CI, 5-35%; p = 0.014) for death from CV causes, 37% (95% CI, 20-50%; p=0.001) for the development of severe HF, 22% (95% CI, 4-37%; p= 0.019) for CHF requiring hospitalization, and 25% (95% CI, 5-40%; p= 0.015) for recurrent MI. | 123; 1115; 1116 | 2231; 1115; 1116 | SAVE, 1992 1386652 (89) |
Investigated the effect of therapy with ACEI ramipril, on survival in pts who had shown clinical evidence of HF at any time after an acute MI. Also, to compare the incidences of progression to severe or resistant HF, nonfatal re-infarction and stroke between the 2 groups.

**RCT**

**AIRE 1993**

8104270 (172)

| 2006; 1014; 992 | Aged ≥18 y, with a definite acute MI 3-10 d before randomization; Clinical evidence of HF at any time since acute MI | Use of an ACEI considered to be mandatory | Mortality from all causes | 1.3 y | Mortality from all causes was significantly lower for pts on ramipril compared to pts on placebo. RR: 27%; 95% CI: 11-40%; p = 0.002. Prespecified secondary outcomes: risk reduction of 19% for the 1st validated outcome—namely, death, severe/resistant HF, MI, or stroke (95% CI: 5% - 31%; p=0.008).

**TRACE 1995**

7477219 (173)

To determine whether pts who LV dysfunction soon after MI benefit from long-term oral ACE inhibition.

**RCT**

| 1749; 876; 873 | Consecutive pts >18 y hospitalized with MI; Criteria for MI: chest pain or electrocardiographic changes, accompanied by >2X increase in one or more cardiac enzymes; LV dysfunction (EF <35%); NYHA class 1 - 41%; BP 121/76; HR 81 | Contraindication to ACEI or a definite need for them; Severe, uncontrolled DM; Hypotension (<125 mmHg); Elevated Scr level (2.3 mg/dL) | Death from any cause | The mortality from all causes at 1 y was 24%. | 24 lives were saved after one mo of treating 1000 pts | During the study period, 304 pts in the trandolapril group died (34.7%), as did 369 in the placebo group (42.3%). RR: 0.78 (95% CI, 0.67 - 0.91; p=0.001). In every subgroup, treatment with trandolapril was associated with a reduction in risk.

**COMET:** Poole-Wilson et al; (2003) 12853193

To compare the effects of carvedilol and metoprolol on clinical outcome in pts with HF

- **RCT Diuretics, ACEIs**
- **NYHA class II-IV**
- **All-cause mortality**
- **Composite endpoint of all-cause mortality, or all-cause admission**

**CIBIS III:** 2005 16143696

Sufficient data do not currently exist to establish the optimum order of initiating chronic HF therapy (ACEI vs. beta blocker). This was the objective of the CIBIS III trial— it compared the effect on mortality and hospitalization of initiating monotherapy with either bisoprolol or enalapril for 6 mo, followed by their combination for 6 to 24 mo.

- **Diuretics 84%; Digoxin 32%**
- **CAD 62%**
- **NYHA class II or III, and LVEF <35% (By echo within the 3 mo)**
- **Clinically stable HF (without clinically relevant fluid retention or diuretic adjustment within 7 d)**

**Treatment with an ACEI, an ARB, or a beta blocker for >7 d during the 3 mo before randomization**

- Heart rate at rest <60 beats/min without a functioning pacemaker
- Supine SBP <100 mm Hg at rest
- SCr ≥ 220 µmol/L
- AV block greater than first degree without a functioning pacemaker
- Obstructive lung disease contraindicating bisoprolol treatment

- **NYHA II or III; mild to moderate CHF**
- **LVEF 29%**
- **Heart rate 75; SBP 134**

**The primary endpoint was time-to-the-first-event of combined all-cause mortality or all-cause hospitalization**

- **Combined endpoint at the end of the monotherapy phase and the individual components of the primary endpoint, at study end and at the end of the monotherapy phase.**
- **CV death**
- **CV hospitalization**

**ITT sample:** 178 pt (35.2%) with a primary end point in the bisoprolol-first group, and 186 (36.8%) in the enalapril-first group (absolute difference -1.6%; 95% CI -7.6 to 4.4%; HR: 0.94; 95% CI 0.77 to 1.16; noninferiority for bisoprolol-first versus enalapril-first treatment, p=0.019)

**Mean of 1.22±0.4 2 y (maximum of 2.10 y).**

Hypotheses: warfarin superior to aspirin and clopidogrel superior to aspirin for HF pt with reduced LVEF in sinus rhythm

Prospective, multicenter RCT, open label (warfarin) or double blind APT group comparing aspirin (162 mg) vs. clopidogrel (75 mg no load) vs warfarin (target INR 2.5)

N=1587; treatment for 1 y; mean fu 1.9 y (stopped early due to poor recruitment)

NYHA II-IV, EF ≤35%, sinus rhythm on entry; on diuretics and ACE-I/ARB or H/N

Reversible HF; contraindicated to any study drug; imminent procedure or surgery; other survival-limiting disease

Efficacy: time to first event of composite (death + nonfatal MI + nonfatal stroke); Safety: major bleeding

Death; nonfatal MI; nonfatal stroke; hospitalization for HF

Efficacy ITT: Primary - No difference warfarin vs. aspirin vs clopidogrel; Secondary - A group with more total and HF hospital admissions; Safety ITT: warfarin=aspirin, both with more major bleeding than clopidogrel

Efficacy PRIMARY: ITT: warfarin vs. aspirin: HR: 0.98; 95% CI: 0.86-1.12; p=0.77. clopidogrel vs. aspirin: HR: 1.08 95% CI: 0.83-1.40; p=0.57. warfarin vs. clopidogrel: HR: 0.89; 95% CI: 0.68-1.16; p=0.39. AT: warfarin superior to aspirin (p=0.0005), warfarin superior to clopidogrel (p=0.0031). SECONDARY endpoints: HF hospitalizations aspirin (22.2%) vs. warfarin (16.5%), p=0.019; Total HF admissions aspirin (218) vs. warfarin (155), p <0.001. Safety PRIMARY: major bleeding warfarin (5.2%) vs. clopidogrel (2.1%), p=0.007; warfarin vs. aspirin (p=NS). POST HOC Ischemic group (N=1163): Strokes warfarin (0) vs. aspirin (1.6), p=0.01; warfarin (0) vs. clopidogrel (2.7%), p=0.0009; Nonischemic group (N=424) Major bleed clopidogrel (0.7%) vs. warfarin (6.3%), p=0.0093. AT analysis (not prespecified): warfarin superior to aspirin (p=0.0095); warfarin superior to clopidogrel (p=0.0031).
Both warfarin (RR=0.60) and aspirin (RR=0.70) were associated with improved survival.

Univariate survival: AC (1 y 77.7%; 95% CI: 71.7-82.4), 3 y 55.1%; 95% CI: 48.7-61.5), 5 y 40.4% [95% CI: 34.1-46.8] vs. no AC (1 y 71.5% [95% CI: 64.9-78.1], 3 y 47.0% [95% CI: 38.6-54.3], 5 y 31.0% [95% CI 24.0-38.0]; p=0.01 for AC vs no AC.

Multivariate: OAT RR:0.60 [95% CI 0.4-0.8], aspirin RR: 0.7 [95% CI 0.5-0.9]

Wojnicz 2006
16596844
Pilot Study: LMWH effects on clinical endpoints in chronic HF secondary to DCM
Prospective, randomized, active treatment control, open label comparing enoxaparin 1.5 mg/kg BID x 14 d, then 1 daily x 3 mos.
N=102 (52 treatment, 50 control), enrolled data on N=85 for analysis; f/u=1 y
N/A
Stable NYHA II-IV, EF ≤ 30% or CTR ≥ 0.60, plus hypotension or systemic or pulmonary edema
Contraindicated to any heparin, T1DM, recent heparin exposure, CAD, Biopsy
Composite [mortality + serious bleeding], secondary endpoints in N=102 (52 treatment, 50 control)
Total survival, BNP, LVEF, echo chamber parameters, NYHA class change, VO2 max, Qol.
Primary: no difference between LMWH and control in reducing vascular events in AF
Secondary: LMWH improves enoxaparin increase 6.5%, p=0.023; 95% CI: 1.01-8.17.

RE-LY
Connolly 2009
19717844
Compare dabigatran vs. warfarin effects on stroke/arterial emboli in pts with AF
Noninferiority, multicenter, prospective RCT, blinded dab (110 or 150 mg BID) or unblinded warfarin (INR 2.0-3.0)
Total N=18,113; median f/u=2.0 y
HF n=5793 (32%); HF on dab 110 mg (n=1937/6015); HF on dab 150 (n=1934/6076); HF on warfarin (n=1922/6022).
AF + ≥1 additional risk factor for stroke (median CHADS2 score 2.1). HF as qualifying criteria needed LVEF <40% or NYHA Class II
Excessive bleeding risk, severe valve disease, stroke <14 d/severe stroke <60 mo, creat clear <30 mL/min
Efficacy: composite [stroke or systemic embolism]; Safety: Major hemorrhage (2 y)
Stroke, systemic embolism, death, MI, PE, TIA, hospitalization
ITT, noninferiority with Cox prop hazards. Subsequent analyses for superiority
Symptomatic HF: multivariate HR for dab 150 vs warfarin, p=0.33; 150 mg dab vs warfarin: stroke 0.64; 95% CI: 0.51-0.81; p=0.001 (p=0.05 for all stroke subgroups).
MI: RR: 1.38; 95% CI 0.11.0-1.91; p=0.048

ACTIVE-W
2006
16765759
Combination clopidogrel + aspirin vs warfarin in reducing vascular events in AF
Prospective open label noninferiority RCT of [clopidogrel 75 mg + aspirin 75-100 mg] vs warfarin (INR 2.0-3.0)
Total N=6706
HF N=2031 (30%)
AF, LVEF <45%
Other need for warfarin, excessive bleeding risk, prev ICH, platelets <50 K, mitral stenosis
Efficacy: First event of [stroke or arterial TEE or MI or vascular death]; Safety: Major hemorrhage
Efficacy: components of primary; Safety: Minor hemorrhage
KM log-rank (time to event)
Total Study: Primary Efficacy: clopidogrel +aspirin: 5.60 events/y vs warfarin 3.93 events/y; RR: 1.44; 95% CI 1.18-1.76; p=0.0003; stroke RR: 1.72; 95% CI: 1.24-2.37; p=0.001

Compare warfarin vs. aspirin vs. both on survival in CHF
Prospective observational population-based, nonrandomized, consecutive hospital survivors of hospitalization, aspirin vs. warfarin at hospital discharge
N=417 with complete data, mean f/u= 5 y; aspirin (30.9%) vs. OAT (28.3%) vs. both (2.4%)
N/A
≥ 1 hospitalization for HF, NYHA II-IV, EF ≤30% or CTR ≥ 0.60, plus hypotension or systemic or pulmonary edema
Failure to meet inclusion criteria (systematic enrollment)
Survival 1 y and 5 y from index hospitalization; stratified by LVEF
None
Both warfarin (RR=0.60) and aspirin (RR=0.70) associated with improved survival
Univariate survival: AC (1 y 77.7%; 95% CI: 71.7-82.4), 3 y 55.1%; 95% CI: 48.7-61.5), 5 y 40.4% [95% CI: 34.1-46.8] vs. no AC (1 y 71.5% [95% CI: 64.9-78.1], 3 y 47.0% [95% CI: 38.6-54.3], 5 y 31.0% [95% CI 24.0-38.0]; p=0.01 for AC vs no AC.
Multivariate: OAT RR:0.60 [95% CI 0.4-0.8], aspirin RR: 0.7 [95% CI 0.5-0.9]
ROCKET AF
Patel 2011
21830957 (196)

Compare rivaroxaban to warfarin in preventing ischemic strokes in pt with nonvalvular AF

Prospective multicenter double-blind double-dummy event-driven noninferiority RCT of rivaroxaban 20 mg/d (15 mg if Cr Cl 30-49 mL/min) vs. warfarin (INR 2-3)

N=14,284 randomized, median f/u=707 d

8909 (rivaroxaban 4467, warfarin 4441) (62.5%)

Nonvalvular AF, CHADS2 ≥2; HF (clinical dx or LVEF ≤35%)

Mitral stenosis, absolute non-AF indication for AC, high risk for anticoagulation

Primary efficacy: composite [ischemic or hemorrhagic stroke + systemic embolism]; Primary safety: composite [major + nonmajor clinically relevant bleeding]

Secondary efficacy: composite stroke + systemic embolism + CV mortality; composite [stroke + systemic embolism + CV mortality + MI]; individual components of primary composite. Secondary safety

Active treatment analysis (by design): rivaroxaban (1.7% per year events) noninferior to warfarin (2.2% per year events) for primary outcome; no difference in safety endpoints; fewer CHN hemorrhage and fatal bleeding in rivaroxaban group. Findings consistent for all subgroups.

Efficacy: Per protocol, rivaroxaban HR: 0.79; 95% CI: 0.66 - 0.96; p<0.001 for noninferiority; HF subgroup ITT p=0.419. Safety superiority of rivaroxaban p=0.02

Belch 1981
7291971 (197)

Effect of low-dose SQ H on lower extremity DVT in pts with HF and pts with chest infections

Prospective, randomized, open label, controlled study SQ H 5000 u q8h x 14 d or until discharge

Total N=100

HF subset n=38 (21 treatment, 17 control)

HF NYHA II-IV, clinical signs of volume overload

“Definite” risk of bleeding, DVT or PE on admission, >2 d bed rest prior to admission

DVT diagnosed by I-125 fibrinogen scanning every 2 d or until discharge

Clinical evidence of bleeding

H reduced demonstrable DVT Total group: DVT (Ctl 26% vs H 4% of treated, p<0.01); 20% had minor bleeding (bruising at injection site), no major bleeding

ARTEMIS
Cohen 2006
16439370 (198)

Safety and efficacy of fondaparinux in reducing VTE in older, moderate-high risk medical inpt

Double-blind, placebo-controlled, block randomized, multicenter RCT of SQ fondaparinux 2.5 mg/d for 6-14 d started within 48 h of admission

N=849 medical inpt, mean 83±1 mo

HF n=160 (fondaparinux 78, placebo 82)

CHF (NYHA III-IV) or acute respiratory illness; expected bed rest >4 d; age >60

High bleeding risk” or contraindicated to anticoagulation, Creat >2.0 mg/dL, contrast allergy, mechanical vent >24 h (total), indication for AC prophylaxis or therapy, life expectancy otherwise <1 mo

Efficacy: DVT diagnosed by contrast venogram (d 5-15), symptomatic VTE (inc PE by imaging or fatal) through d 15, Safety: major bleeding

Efficacy: composite [Total VTE + bleeding + death at 1 mo]; Safety: composite [death or minor bleeding]

ITT (efficacy): all pt with ≥1 dose of drug (safety); HF pts=predefined subgroup. Fishers Exact and log-rank HF subgroup: Primary: fondaparinux 7/78 (9%) vs placebo 10/82 (12.2%), p=NS, Primary safety: p=NS (1 bleed in each group)

</table>
with a pacemaker–defibrillator, and optimal pharmacologic therapy alone in a population with advanced HF and intraventricular conduction delays.

| CARE-HF | To analyze the effects of cardiac resynchronization on the risk of complications and death among pts who were receiving standard medical therapy for moderate or severe HF and cardiac dyssynchrony. | RCT | 813; 409; medical therapy*: 404 | 29.4 | ACE-Is, beta-blockers, and spironolactone | 3 or 4 | <35 | >120 | • not randomized  
• lacked non-CRT control group  
• enabled ICD implantation only in one study arm  
• had cross-over study design  
• did not report the clinical outcomes of interest such as  
• reported clinical outcomes without any relation to specific limited QRS ranges. | 120-159 (n 290); >159 (n 505) | All cause mortality or hospitalizations for major CV event including HF hospitalization | Primary endpoint was reached by 159 pts in the cardiac-resynchronization group, as compared with 224 pts in the medical-therapy group (39 % vs. 55%; HR: 0.63; 95 % CI: 0.51-0.77; p<0.001).

There were 82 deaths in the cardiac-resynchronization group, as compared with 120 in the medical-therapy group (20% vs. 30%; HR: 0.64; 95 %CI: 0.48-0.85; p<0.002).

As compared with medical therapy, cardiac resynchronization reduced the interventricular mechanical delay, the end-systolic volume index, and the area of the mitral regurgitant jet; increased the LVEF; and improved symptoms and the QoL (p<0.01 for all comparisons).

Risk of the combined endpoint of death from or hospitalization for HF was reduced by 34% in the pacemaker group (p<0.002) and by 40% in the pacemaker–defibrillator group (p<0.001 for the comparison with the pharmacologic-therapy group).

Pacemaker reduced the risk of the secondary endpoint of death from any cause by 24% (p=0.059), and a pacemaker–defibrillator reduced the risk by 36% (p=0.003).
| Study | RCT | 610; 419; CRT-off: 191 | 12 | ACE-Is, beta blockers, and spironolactone | 1 or 2 | <40 | >120 | • not randomized  
• lacked non-CRT control group

| Aim of trial was to determine whether CRT with biventricular pacing would reduce the risk of death or HF events in pts with mild cardiac symptoms, a reduced EF, and a wide QRS complex. | | | | | | | | Primary end point occurred in 17.2% of the CRT–ICD group and in 25.3% of the ICD-only group. CRT–ICD group HR: 0.66; 95% CI: 0.52-0.84; p=0.001. The benefit did not differ significantly between pts with ischemic cardiomyopathy and those with nonischemic cardiomyopathy. CRT superiority was driven by a 41% reduction in the risk of HF events evident primarily in a prespecified subgroup of pts with a QRS duration ≥150 msec. CRT was associated with a significant reduction in LV volumes and improvement in the EF. There was no significant difference between the two groups in the overall risk of death, with a 3% annual mortality rate in each treatment group. SAEs were infrequent in the 2 groups. |
Aim of trial was to evaluate whether adding CRT to an ICD and optimal medical therapy might reduce mortality and morbidity among such pts.

PROSPECT

Circulation. 2008;117: 2608-2616. 18458170

Aim of trial was to evaluate selected, predefined baseline echocardiographic parameters for their ability to predict clinical and echocardiographic response to CRT.

prospective, multicenter, nonrandomized study (observational)

498-enrolled; 467-implanted; Not applicable

Medical therapy, unless contraindicated, was to include an ACE-I or ARB for at least 1 mo before enrollment and a beta blocker started at least 3 mo before and unchanged for at least 1 mo before enrollment

3 or 4

≤35

>130

N/A

12 echocardiographic parameters of dyssynchrony, based on both conventional and tissue Doppler-based methods, were evaluated after site training in acquisition methods and blinded core laboratory analysis.

Clinical composite score was improved in 69% of 426 pts, whereas LV end-systolic volume decreased ≥15% in 56% of 286 pts with paired data. The ability of the 12 echo parameters to predict clinical composite score response varied widely, with sensitivity ranging from 6%-74% and specificity ranging from 35%-91%; for predicting LVESV response, sensitivity ranged from 9%-77% and specificity from 31%-93%. For all the parameters, the area under the ROC curve for positive clinical or volume response to CRT was <0.62. There was large variability in the analysis of the dyssynchrony parameters.

To determine whether estimated hemodynamics from history and physical examination reflect invasive measurements and predict outcomes in advanced HF.

Retrospective analysis

Compared H&P estimates of filling pressures and cardiac index with invasive measurements in 194 pts in the ESCAPE trial. H&P estimates were compared with 6-mo outcomes in 388 pts enrolled in ESCAPE.

Critevel >3.5 mg/dL (308.4 μmol/L), or prior use of dobutamine or dopamine >3 μg/kg/min, or any prior use of milrinone during the current hospitalization.

RAP was <8 mm Hg in 82% of pts with RAP estimated from jugular veins as <8 mm Hg, and was >12 mm Hg in 70% of pts when estimated as >12 mm Hg. From the H&P, only estimated RAP ≥12 mm Hg (OR: 4.6; p<0.001) and orthopnea ≥2 pillows (OR: 3.6; p<0.05) were associated with PCWP ≥30 mm Hg. Estimated cardiac index did not reliably reflect measured cardiac index (p=0.09), but "cold" versus "warm" profile was associated with lower median measured cardiac index (1.75 vs. 2.0 L/min/m²; p=0.004). In Cox regression analysis, discharge "cold" or "wet" profile conveyed a 50% increased risk of death or rehospitalization. In advanced HF, the presence of orthopnea and elevated jugular venous pressure are useful to detect elevated PCWP, and a global assessment of inadequate perfusion ("cold" profile) is useful to detect reduced cardiac index. Hemodynamic profiles estimated from the discharge H&P identify pts at increased risk of early events.

To estimate the impact of the PAC device in critically ill pts.

Meta-analysis

MEDLINE (1985-2005), the Cochrane Controlled Trials Registry (1988-2005), the National Institutes of Health ClinicalTrials.gov database, and the US Food and Drug Administration Web site for RCTs in which pts were randomly assigned to PAC or no PAC were searched. Results from the ESCAPE trial of pts with severe HF were also included. Search terms included pulmonary artery catheter, right heart catheter, catheter, and Swan-Ganz.

N/A

HR for mortality 1.04. In critically ill pts, use of the PAC neither increased overall mortality or d in hospital nor conferred benefit. Despite almost 20 y of RCTs, a clear strategy leading to improved survival with the PAC has not been devised. The neutrality of the PAC for clinical outcomes may result from the absence of effective evidence-based treatments to use in combination with PAC information across the spectrum of critically ill pts. Use of the PAC was associated with a higher use of inotropes (OR: 1.58; 95% CI: 1.19-2.12; p=.002) and IV vasodilators (OR: 2.35; 95% CI: 1.75-3.15; p<.001).

p=0.53 The combined OR for mortality was 1.04 (95% CI: 0.90-1.20; p=.59). The difference in the mean number of d hospitalized for PAC minus the mean for no PAC was 0.11 (95% CI: -0.51-0.74; p=.73).

Estimated RAP OR: 4.6, orthopnea OR: 3.6 p<0.05 posthoc, small sample heterogeneity of studies
| Allen LA, Rogers JG, Warnica JW et al. High mortality without ESCAPE: the registry of HF pts receiving pulmonary artery catheters without randomization. J Card Fail 2008 October;14(8):661-9 | To characterize pts enrolled in ESCAPE Registry | Registry | 439 | ESCAPE sites enrolled 439 pts receiving PAC without randomization in a prospective registry. Baseline characteristics, pertinent trial exclusion criteria, reasons for PAC use, hemodynamics, and complications were collected. Survival was determined from the National Death Index and the Alberta Registry. Much sicker pts than ESCAPE N/A | Registry pts had longer hospitalization (13 vs 6 d, p<.001) and higher 6-mo mortality (34% vs 20%, p<.001) than trial pts. On average, registry pts had lower blood pressure, worse renal function, less neurohormonal antagonist therapy, and higher use of IV inotropes compared with trial pts. Although clinical assessment anticipated less volume overload and greater hypoperfusion among the registry population, measured filling pressures were similarly elevated in the registry and trial pts, whereas measured perfusion was slightly higher among registry pts. 6 mo mortality 34% |
| Positive Pressure Ventilation Studies | Noninvasive ventilation CPAP or NIPPV appears to be of benefit in the immediate treatment of pts with acute cardiogenic pulmonary edema and may reduce mortality. To determine whether noninvasive ventilation reduces mortality and whether there are important differences in outcome associated with the method of treatment (CPAP or NIPPV). | RCT | 1069 (randomize d to standard oxygen therapy, (n=367) versus CPAP (5 to 15 cm of water) (n=346) OR NIPPV (inspiratory pressure, 8 to 20 cm of water; expiratory pressure, 4 to 10 cm of water) (n=356). | Age > 16 y, clinical diagnosis of acute cardiogenic PE, PE on chest radiograph, respiratory rate >20 breaths/min, and arterial hydrogen ion concentration >45 nmol/L (pH <7.35). | There was no significant difference in 7-d mortality between pts receiving standard oxygen therapy (9.8%) and those undergoing noninvasive ventilation (9.5%, P=0.87). There was no significant difference in the combined endpoint of death or intubation within 7 d between the two groups of pts undergoing noninvasive ventilation (11.7% for CPAP and 11.1% for NIPPV, P=0.81). In pts with acute cardiogenic PE, noninvasive ventilation induces a more rapid improvement in respiratory distress and metabolic disturbance than does standard oxygen therapy but has no effect on short-term mortality. CPAP or NIPPV MAY be considered as adjunctive therapy in pts with severe acute cardiogenic pulmonary oedema in the presence of severe respiratory distress or when there is a failure to improve with pharmacological therapy. As compared with standard oxygen therapy, noninvasive ventilation was associated with greater mean improvements at 1 h after the beginning of treatment in pt-reported dyspnea (treatment difference, 0.7 on a visual-analogue scale ranging from 1 to 10; 95% CI: 0.2-1.3; p=0.008), heart rate (treatment difference, 4 beats/min; 95% CI: 1-6; p=0.004), acidosis (treatment difference, pH 0.03; 95% CI: 0.02-0.04; p=0.001), and hypercapnia (treatment difference, 0.7 kPa [5.2 mm Hg]; 95% CI: 0.4-0.9; p<0.001). |
To systematically review and quantitatively synthesize the short-term effect of noninvasive ventilation on major clinical outcomes.

**Meta-analysis**

15 trials comparing noninvasive ventilation to conventional oxygen therapy in pts with acute PE. Comparisons of different techniques, either CPAP or bilevel NIPSV, were also included.

| N/A | Overall, noninvasive ventilation significantly reduced the mortality rate by nearly 45% compared with conventional therapy (RR: 0.55; 95% CI: 0.40-0.78; p=.72 for heterogeneity). The results were significant for CPAP (RR: 0.53; 95% CI: 0.35-0.81; p=.44 for heterogeneity) but not for NIPSV (RR: 0.60; 95% CI: 0.34-1.05; p=.76 for heterogeneity), although there were fewer studies in the latter. Both modalities showed a significant decrease in the "need to intubate" rate compared with conventional therapy: CPAP (RR: 0.40; 95% CI: 0.27-0.58; p=.21 for heterogeneity), NIPSV (RR, 0.48; 95% CI: 0.30-0.76; p=.24 for heterogeneity), and together (RR: 0.43; 95% CI: 0.32-0.57; p=.20 for heterogeneity). There were no differences in intubation or mortality rates in the analysis of studies comparing CPAP and NIPSV. Noninvasive ventilation reduces the need for intubation and mortality in pts with acute cardiogenic pulmonary edema. Although the level of evidence is higher for CPAP, there are no significant differences in clinical outcomes when comparing CPAP vs. NIPSV. |

Severe Cardiogenic Shock: Patient, Role of PVADs to Bridge to Recovery or Bridge/Transplant

| Kar B, Gregoric ID, Basra SS, Idolchik GM, Loyaika P. The percutaneous ventricular assist device in severe refractory cardiogenic shock. *J Am Coll Cardiol* 2011 February 8;57(6):688-696. 20950980 (259) | To determine the efficacy and safety of the pVAD in pts in SRCS despite intra-aortic balloon pump and/or high-dose vasopressor support. Prospective Cohort 117 Cardiogenic shock pts with a SBP of 90 mm Hg, a cardiac index of 2.0 l/(min·m²) and evidence of end-organ failure despite IABP/pressor support. A total of 117 pts with SRCS implanted with TandemHeart pVAD were studied, of whom 56 pts (47.9%) underwent active cardiopulmonary resuscitation immediately before or at the time of implantation. Cardiogenic shock pts with a SBP of 90 mm Hg, a cardiac index of 2.0 l/(min·m²) and evidence of end-organ failure despite IABP/pressor support. A total of 117 pts with SRCS implanted with TandemHeart pVAD were studied, of whom 56 pts (47.9%) underwent active cardiopulmonary resuscitation immediately before or at the time of implantation. | N/A 56 (47.9%) of the 117 pts (41 of 80 [51.2%] with ICM; 15 of 37 [40.5%] with NICM) were undergoing CPR during pVAD placement. The average time from CPR onset to TandemHeart implantation was 65.6+/−41.3 min. 80 pts had ischemic and 37 pts had nonischemic cardiomyopathy. The average duration of support was 5.8 d. After implantation, the cardiac index improved from median 0.52 (interquartile range [IQR]: 0.8) l/(min·m²) to 3.0 (IQR: 0.9) l/(min·m²) (p<0.001). The SBP and mixed venous oxygen saturation increased from 75 (IQR: 15) mm Hg to 100 (IQR: 15) mm Hg (p=0.001) and 49 (IQR: 11.5) to 69.3 (IQR: 10) (p=0.001), respectively. The PCWP, lactic acid level, and Cr level decreased, respectively, from 31.53 to 10.2 mm Hg to 17.29 (IQR: 10.82 mm Hg (p=0.001), 24.5 (IQR: 74.25) mg/dl to 11 (IQR: 92) mg/dl (p=0.001), and 1.5 (IQR: 0.95) mg/dl to 1.2 (IQR: 0.9) mg/dl (p=0.009). The mortality rates at 30 d and 6 mo were 40.2% and 45.3%, respectively. |
To characterize whether PVAD may offer effective treatment for cardiogenic shock

Case Series 18

VADs were implanted in 18 consecutive pts who had cardiogenic shock after MI.

Mean duration of cardiac assistance was 4±3 d. Mean flow of the VAD was 3.2±0.6 L/min. Before support, cardiac index was 1.7±0.3 L/min per m(2) and improved to 2.4±0.6 L/min per m(2) (p<0.001). Mean blood pressure increased from 63±8 mm Hg to 80±9 mm Hg (p<0.001). PCWP, central venous pressure, and pulmonary artery pressure were reduced from 21±4, 13±4, and 31±8 mm Hg to 14±4, 9±3, and 23±6 mm Hg (all p<0.001), respectively. Overall 30-d mortality rate was 44%.

To evaluate the efficacy of a PVAD as a bridge to LVAD implantation in pts with severe refractory cardiogenic shock as a bridge to long-term left ventricular assist device implantation.

Case Series 18

18 pts in SRCS received a PVAD as a bridge to LVAD placement or orthotopic heart transplantation. 6 pts had ischemic cardiomyopathy, and 12 had nonischemic cardiomyopathy. At the time of PVAD placement, 17 were receiving IABP support, and 10 were undergoing cardiopulmonary resuscitation.

The mean duration of PVAD support was 4.2 ± 2.5 d. During this time, the cardiac index improved from 0.86 ± 0.66 to 2.50 ± 0.93 liters/min/m2 (p < 0.001), SBP improved from 72 ± 11 to 98 ± 15 mm Hg (p<0.001), and systemic mixed venous oxygenation improved from 37 ± 7 to 62 ± 6 mm Hg (p < 0.001). We terminated life support in 4 of the 18 pts before LVAD placement; 14 were successfully bridged to LVAD or heart transplantation. The mortality rate was 27% at 30 d and 33% at 6 mo. There were no PVAD-associated deaths. CONCLUSION: In pts with terminal hemodynamic collapse, PVAD support is an effective bridging therapy to LVAD and appears to be a viable alternative to other invasive methods of support.

A meta-analysis of controlled trials of PVADs vs. intra-aortic balloon pump counterpulsation for treatment of cardiogenic shock: a meta-analysis of controlled trials.

Meta-Analysis 2 trials evaluated the TandemHeart and a recent trial used the Impella device

After device implantation, percutaneous LVAD pts had higher CI (MD 0.35 L/min/m(2), 95% CI: 0.09-0.61), higher MAP (MD 12.6 mmHg, 95% CI: 3.6-22.0), and lower PCWP (MD -5.3 mm Hg, 95% CI: -9.4 to -1.2) compared with IABP pts. Similar 30-day mortality (RR: 1.06; 95% CI: 0.68-1.66) was observed using percutaneous LVAD compared with IABP. No significant difference was observed in incidence of leg ischaemia (RR: 2.59, 95% CI: 0.75-8.97) in percutaneous LVAD pts compared with IABP pts. Bleeding (RR: 2.35, 95% CI: 1.40-3.93) was significantly more observed in TandemHeart pts compared with pts treated with IABP. Although percutaneous LVAD provides superior haemodynamic support in pts with cardiogenic shock compared with IABP, the use of these more powerful devices did not improve early survival. These results do not yet support percutaneous LVAD as first-choice approach in...

| p=0.71, d of hospitalization for CV causes within 60 d p<0.02, death or readmission within 60 d p=0.001 for treatment failure due to AE |

Did not directly address pts with ADHF for whom inotropic therapy was felt be essential (eg, low cardiac output state with tissue hypoperfusion). Not structured to assess pts for NSVT, a known adverse effect of milrinone. Inadequately powered to evaluate mortality.

Sustained hypotension, (SBP< 80 mm Hg for more than 30 min, requiring intervention); 10.7% with milrinone, 3.2% with placebo, p<0.001 Significant atrial arrhythmias during index hospitalization, 4.6% milrinone, 1.5% placebo, p=0.004
To assess the interaction between HF etiology and response to milrinone in decompensated HF.

**Post-hoc analysis**

ACEI 70%, blocker 23%, Amiodarone 15%, Digoxin 73%, 940 (total), 477 (randomized to milrinone), 242 (ICM, milrinone), 235 (ICM, placebo), 229 (NICM, milrinone), 465 ICM (51% of total), 242 ICM (49% of total), Age >18 y, LVEF < 40% with the past year, NYHA II-IV symptoms, NYHA II-IV at baseline, NYHA II-IV at 60 d.

Main secondary outcome included the proportion of cases failing therapy because of adverse events or worsening HF 48 hr after initiation of therapy. Other secondary outcomes included the proportion of pts achieving target doses of ACEI therapy and time to achieve target dose, symptoms, improvement in HF score, length of initial hospitalization, d of hospitalization for CV events from initial hospital discharge to 60 d, d of hospitalization for CV events within 30 d after randomization, all-cause hospitalization, and mortality.

Other secondary outcomes included the proportion of pts achieving target dosing of ACEI at hospital discharge (49%) compared with ischemic HF pts (36%). Treatment failure while on the study drug was similar between the 2 groups (14.2% for ischemic vs. 15.2% for nonischemic pts). Primary endpoint, p=0.2, 60d mortality, P=0.03. Combined endpoint, p=0.7. Able to reach target ACEI dose, p=0.001. N/A. Retrospective study; No data collected on the level of care that pts received (i.e., ICU vs. monitored bed), which potentially could have affected the results of study; Imbalanced follow up between etiologic groups (4 pts in ischemic group vs. 8 pts in nonischemic group lost to follow-up).

In pts with ischemic HF, milrinone tended to be associated with prolonged hospitalization and higher mortality. Composite of death or hospitalization at 60 d was 42% for ischemic pts treated with milrinone and 36% for those treated with placebo (p=0.01 for etiology-treatment interaction). In hospital mortality for milrinone-treated pts with ischemic HF was 5.0% vs. 1.6% for placebo (p=0.04 for etiology-treatment interaction).
### Baseline QoL data did not differ between the 2 groups.

### Observation an analysis retrospective analysis of medical management choice of IV med Non-randomized Differences in clinical severity between subgroups

© American College of Cardiology Foundation and American Heart Association, Inc.
Enoximone in Intravenous Inotropic-Dependent Subjects Study (EMOTE), Feldman AM, 2007

To determine whether low-dose oral enoximone could wean pts with ultra-advanced HF (UA-HF) from intravenous (IV) inotropic support

RCT

Diacetic 68%, ACEI 62%, ARB 18%, blocker 40%, digoxin 70%, antithrombin 37%, ICD 42%, Milrinone 62%, dobutamine 38%, both dobutamine and milrinone 3%

Continuous IV inotrope 74%

Age > 18 yrs, NYHA III or IV CHF, Ongoing need for > 5 d of continuous IV inotropic therapy or the need for intermittent IV inotropic therapy with either dobutamine (≥2 μg/kg/min) or milrinone (≥0.125 μg/kg/min) for ≥6 h at a frequency of >1x/wk, and for ≥4 wk. LVEF of ≤25% by radionuclide ventriculography or ≤30% by 2-dimensional echocardiography. Cardiac dilatation (LVEDD ≥2.7 cm/m² or ≥5.4 cm as measured by 2-dimensional echocardiography within 26 wk)

Received a placebo

Time to reinitiation of IV inotropic therapy. Total number of d on IV inotropic therapy. Total number of hospitalization for all cause, CV, and CV/vascular events; Measurements of symptoms (SAS scale, NYHA) and pt well-being (Visual Analog Scale, global assessments) at 4 and 26 wk.

Unadjusted primary end point p=0.14, adjusted for etiology p= 0.17

Rebound of CHF in 54% enoximone vs 52% placebo, NS

Dyspnea, 5% enoximone vs 0% placebo, P<0.05
### Use and Impact of Inotropes and Vasodilator Therapy in Hospitalized Pts with Severe HF (ESCAPE), Elkayam U, Am Heart J 2007 17174645

To determine 6-mo risks of all-cause mortality and all-cause mortality plus rehospitalization associated with the use of vasodilators, inotropes, and their combination:

- **ACEI/ARB**: 98%
- **Diuretics**: 92%
- **b-Blockers**: 42%
- **IV inotrope**: 28%
- **IV vasodilator**: 28%

#### Prospective Randomized Milrinone Survival Evaluation (PROMISE), Packer

To determine the effect of oral milrinone on the mortality of NYHA III-IV CHF x ≥3mo LVEF ≤35%

- **NYHA III-IV CHF x ≥3mo**: 1088 (milrinone), 527 (placebo)
- **54% ICM**:
- **Obstructive valvular disease**: Active myocarditis HCM or cardiac disease
- **NYHA III-IV**: 100%, NYHA III-IV 58%, NYHA IV 42%

#### All-cause mortality

- **CV mortality**: No. of hospitalizations, Addition of vasodilators for treatment of worsening Hf.
- **NYHA III-IV**: 12mo mortality
- **NYHA III-IV**: 12mo mortality
- **NYHA III-IV**: Nominal P=0.038.
- **CV mortality**: Nominal P=0.01-0.61.

#### All-cause mortality

- **All-cause mortality**: 6mo mortality adjusted, p, 95% CI
- **Inotrope**: 1.10-4.15, p=0.024
- **Both inotrope and vasodilator**: 2.34-9.90, p<0.001
- **6mo mortality or rehosp (adjusted)**
- **Inotrope**: 1.37-2.82, p<0.001
- **Both inotrope and vasodilator**: 1.88-4.48, p<0.001

#### Background medical management is outdated and suboptimal

- **1.8% milrinone v 0.9% placebo**
pts with severe chronic HF who remained symptomatic despite conventional therapy and ACEI for > 4 wk

amyloid
Uncorrected thyroid disease
Malfunctioning artificial heart valve

Symptoms, Adverse reactions

of adverse effect of milrinone; median duration of follow-up, 6.1 mo

associated with 28% increase in mortality; Log-rank test, milrinone associated with 34% increase in CV mortality

P=0.007

Continuous intravenous dobutamine is associated with an increased risk of death in pts with advanced HF. Insights from the Flolan International Randomized Survival Trial (FIRST), O'Connor CM, 1999 10385768

To evaluate clinical characteristics and outcomes of pts with advanced HF receiving continuous intravenous dobutamine in the FIRST Trial (Flolan International Randomized Survival Trial).

Post-hoc analysis

N/A

471; 80 (dobutamine); 391 (no dobutamine)

NYHA IIIB or IV HF for >1 mo while receiving a regimen including a loop diuretic, digitalis glycoside, and an ACEI, unless contraindicated.

LVEF <35% by a multigated angiocardiogram performed within 3 mo of enrollment, unless the pt was being treated with an IV inotropic agent, in which case LVEF <55% was accepted.

Pts receiving IV vasoactive medications were required to have not responded to an attempt to wean from the medicines

SBP<80 mm Hg; Significant valvular stenosis; Anticipated revascularization or valvular surgery; MI within 3 mo; Uncontrolled tachycardia/ tachyarrhythmias; Unstable or symptom-limiting angina; Requirement for a mechanical assist device to maintain life; Major change in IV vasoactive medications within 12 hr of randomization; CHF caused by uncontrolled thyroid disease, myocarditis, high output failure, or infiltrative cardiomyopathy; Significant

No dobutamine

47% NYHA II
53% NYHA III
11% NYHA IV

Occurrence of clinical events from the FIRST trial, including worsening HF, need for mechanical assist device, resuscitation from sudden cardiac death, MI, and death

QoL measures

NA

The dobutamine group had a higher occurrence of first event (85.3% vs 64.5%) and a higher mortality rate (70.5% vs 37.1%) compared with the no dobutamine group. No difference in QOL between groups.

Primary endpt

1st event p=0.0006

Death 70.5% dobutamine vs 64.5% no dobutamine, p=0.0006

Observation

al analysis

No details provided regarding duration and dose of dobutamine

At 6 mo

First event 85.3% dobutamine vs 64.5% no dobutamine, p=0.0006

Death 70.5% dobutamine vs 37.1% no dobutamine, p=0.0001
within 1 wk of enrollment. Ineligibility for cardiac transplantation and eligibility for long-term oral anticoagulation therapy were also required.

congenital heart disease with shunts, valvular or vascular obstruction; Substance or alcohol abuse within 1 year; Moderate or severe lung disease; Other comorbid conditions likely to shorten survival; Current use of another investigational drug or device.

LVAD as Destination for pts undergoing intravenous inotropic therapy: a subset analysis from REMATCH, Stevenson LW, 2004 15313942 (284)

To analyze outcomes in pts undergoing inotropic infusions at randomization for LVAD destination therapy

Post-hoc analysis
91 (on inotrope at randomization)
LVAF <25% NYHA IV symptoms for 60 of 90 d despite attempted therapy with ACEI, diuretics, and digoxin. Peak VO2 <12-14 mL/kg/min with evidence of anaerobic metabolism, Dependence on IV inotropic agents supported by completion of a weaning failure form.
Advanced age, Diabetes with end-organ damage, Scr >2.5 mg/dL for >90 d following randomization .
All-cause mortality during the 180 d following randomization .
QoL at 1 y
1 y Mortality: LVAD 51% OMM 76% p=0.0014
2 yr Mortality: LVAD 72% OMM 89%
Enrollment 5/06-7/01;
In pts undergoing inotropic therapy at randomization, 1 y survival with LVAD was 49% vs 24% for OMM and by 2 y, 28% were alive with LVAD group compared with 11% in OMM group (p=0.0014).

Investigation of Nontransplant-Eligible Pts Who Are Inotrope Dependent (INTEPID Trial), Rogers JG, 2007 17707178 (286)

To evaluate the impact of LVAD support on survival and QoL in inotrope-dependent HF pts ineligible for cardiac transplantation
Prospective randomized clinical trial
55 Adults with inotrope-dependent stage D HF, LVEF < 25%, NYHA IV symptoms for > 3 mo before enrollment and were not candidates for cardiac transplantation Treated with maximally tolerated doses of ACEI, beta-blockers, digoxin, diuretics, and/or other vasodilators.
BSA <1.5 m2 Contraindication to chronic anticoagulation Presence of a mechanical aortic valve constituted an exclusion criterion for LVAD support CVA or TIA within 6 mo before enrollment, a 70% carotid stenosis, or an ulcerated carotid plaque. Unresolved drug or alcohol dependency Active systemic infection Scr >5.0 mg/dL, Tbil >5.0 mg/dL Mechanical ventilatory support for >48 h at the time of enrollment Comorbid medical condition limiting life expectancy < 2 y
All-cause mortality at 6 mo
AEs, functional capacity HRQoL
1st y mortality 73% (LVAD) vs 89% (OMT) 6mo mortality: 54% (LVAD) vs 78% (OMT)
Enrollment 39 mo (3/00-5/03); 12 mo follow-up
6 mo survival 46% (LVAD) vs 22% (OMT) (HR 0.47; 95% CI 0.23-0.93; p=0.03) 1 y survival 27% (LVAD) vs 11% (OMT) Absolute reduction of 1 y mortality by 16% with LVAD (HR: 0.48; 95% CI: 0.25-0.85; p=0.02)

Advanced HF treated with continuous-flow LVAD, (HeartMateII DT), Slaughter MS, 2009 19920051 (287)

To compare the outcomes of pts ineligible for cardiac transplantation with pulsatile versus continuous flow
RCT 200 Age >18 y BSA > 1.5m2 for a pt to be randomized HM XVE - HM II. If BSA < 1.5 m2and > 1.2 m2, the pt must meet the remaining criteria and can be enrolled in the Small Size HF is due to uncorrected thyroid disease, obstructive cardiomyopathy, pericardial disease, amyloidosis, active myocarditis or RCM. Technical obstacles, which pose an inordinately high surgical risk, in the
The primary composite endpoint was, at 2 y, survival free from disabling stroke and reoperation to
Secondary endpoints included survival, frequency of AE, the QoL, and functional capacity.
1st y mortality: 32% (continuous flow LVAD) vs 42% (pulsatile flow LVAD)
Enrollment 5/05-5/07 (2 y) Follow-up >2 y or until death, cardiac transplant, or
The primary composite endpoint was achieved in more pts assigned to receive a continuous-flow LVAD than in those assigned to receive a pulsatile-flow LVAD (46% vs. 11%).
Higher complication rate with pulsatile LVAD (p<0.001) Pump replacement Sepsis Respiratory failure Renal failure RV failure requiring extended inotrope Rehospitalization

Investigation of Nontransplant-Eligible Pts Who Are Inotrope Dependent (INTEPID Trial), Rogers JG, 2007 17707178 (286)

To evaluate the impact of LVAD support on survival and QoL in inotrope-dependent HF pts ineligible for cardiac transplantation
Prospective randomized clinical trial
55 Adults with inotrope-dependent stage D HF, LVEF < 25%, NYHA IV symptoms for > 3 mo before enrollment and were not candidates for cardiac transplantation Treated with maximally tolerated doses of ACEI, beta-blockers, digoxin, diuretics, and/or other vasodilators.
BSA <1.5 m2 Contraindication to chronic anticoagulation Presence of a mechanical aortic valve constituted an exclusion criterion for LVAD support CVA or TIA within 6 mo before enrollment, a 70% carotid stenosis, or an ulcerated carotid plaque. Unresolved drug or alcohol dependency Active systemic infection Scr >5.0 mg/dL, Tbil >5.0 mg/dL Mechanical ventilatory support for >48 h at the time of enrollment Comorbid medical condition limiting life expectancy < 2 y
All-cause mortality at 6 mo
AEs, functional capacity HRQoL
1st y mortality 73% (LVAD) vs 89% (OMT) 6mo mortality: 54% (LVAD) vs 78% (OMT)
Enrollment 39 mo (3/00-5/03); 12 mo follow-up
6 mo survival 46% (LVAD) vs 22% (OMT) (HR 0.47; 95% CI 0.23-0.93; p=0.03) 1 y survival 27% (LVAD) vs 11% (OMT) Absolute reduction of 1 y mortality by 16% with LVAD (HR: 0.48; 95% CI: 0.25-0.85; p=0.02)

Female pts of childbearing potential must agree to use adequate contraception to prevent pregnancy.

Un合格 for cardiac transplant.

VO2max < 14 mL/kg/min or <50% of predicted VO2max with attainment of anaerobic threshold, if not contraindicated due to IV inotropes, angina or physical disability. LVEF is ≤ 25%.

Judgment of the investigator. Ongoing mechanical circulatory support other than IABP. BMI ≥40 kg/m2. Positive pregnancy test. Presence of mechanical AV that will not be converted to a bioprosthesis. History of cardiac transplant or cardiomyoplasty. Platelet count < 50,000. Untreated aortic aneurysm > 5 cm. Psychiatric disease, irreversible cognitive dysfunction, psychosocial issues that are likely to impair compliance. Active, uncontrolled infection. Intolerance to anticoagulant or antiplatelet therapies or any other peri/post operative therapy that may be required. INR > 2.5, not due to anti-coagulant therapy, or Plavix within 5 days. AST, ALT, or total bilirubin > 5x normal or biopsy proven liver cirrhosis. Severe COPD or restrictive lung disease. Fixed pHTN with a PVR >8 Wood units. Stroke within 90 d. or cerebral vascular disease with >80% extra cranial stenosis. SCR >3.5 mg/dl or on dialysis. Significant peripheral vascular disease with rest pain.

Repair or replacement of the device.

Explant of LVAD

On the basis of the at-treated analysis, the Kaplan–Meier estimate of actuarial survival was significantly better for pts who had a continuous-flow LVAD as compared with those with a pulsatile-flow LVAD.

Improvements in functional status by NYHA Class and 6MWT did not differ between the two groups.

Primary composite endpoint: HR 0.38; 95% CI: 0.27 to 0.54; p=0.001

Actuarial survival, RR: 0.54 95% CI, 0.34 to 0.86; p=0.008
| Use of a continuous-flow device in pts awaiting heart transplantation (HMII BTT), Miller LW, 2007 17761592 (289) | To assess the efficacy of continuous-flow LVAD for providing hemodynamic support of at least 6 mo to pts awaiting heart transplantation | Cohort 133 Transplant listed. BSA > 1.2 m2. NYHA IV HF symptoms. Female pts of childbearing potential must agree to use adequate contraception On inotropic support, if tolerated. Despite medical therapy, the pt must meet one of the following criteria: a. No contraindication for Status 1A listing b. No contraindication for Status 1B listing PCWP or PAD > 20 mmHg, CI < 2.2 L/min/m2 or SBP < 90 mmHg | HF due to uncorrected thyroid disease, obstructive/restrictive cardiomyopathy, pericardial disease, or amyloidosis. Technical obstacles, which pose an incomodely high surgical risk. Ongoing mechanical circulatory support other than IABP BMI > 40 kg/m2. Positive pregnancy test Mechanical aortic valve that will not be converted to a bioprosthesis Hx of cardiac transplant. Platelet count <50,000/mL. Untreated aortic aneurysm > 5cm. Psychiatric dz irreversible cognitive dysfunction, psychosocial issue Active uncontrolled infection. Intolerance to anticoagulant or antiplatelet therapies or any other peri/post operative therapy that may be required Any one of the following | The principal outcomes were the proportions of pts who, at 180 d, had undergone transplantatio n, had undergone explantation of the device because of recovery of ventricular function, or had ongoing mechanical support and remained eligible for transplantatio n (i.e., were not removed from the waiting list owing to irreversible complications or clinical | Secondary outcomes included overall survival, survival while receiving device support, survival after transplantatio n, frequency of AEs, assessment of functional class by a 6-min walk test, independent evaluation of NYHA functional class by a physician, and QoL. | 1 y mortality 32% | Enrollment 3/05-5/06 (15mo); follow-up through 180d | 75% reached principal outcomes 18.8% died before 180d of support | Bleeding requiring pRBCs Local infection, non-LVAD Ventricular arrhythmias Sepsis Right HF |

- Risk factors for and indicators of severe end-organ dysfunction or failure:
  - a) INR >2.5 not due to anticoagulant therapy or Plavix within 5 d.
  - b) Total bilirubin >5mg/dl or shock liver (AST, ALT >2,000), or biopsy proven liver cirrhosis.
  - c) Severe COPD or severe restrictive lung disease.
  - d) Fixed pulmonary hypertension, with a recent PVR >6 Wood units,
  - e) Unresolved stroke or uncorrectable cerebrovascular disease.
  - f) Scr >3.5 mg/dL or the need for chronic dialysis.
  - g) Significant peripheral vascular disease with rest pain or ulceration
  - Moderate to severe aortic insufficiency without plans for AVR
  - Participation in any other clinical investigation

**Extended Mechanical Circulatory Support with a Continuous-Flow Rotary LVAD (HMII BTT), Pagani FD, 2009**

To evaluate the use of a continuous-flow rotary LVAD as a bridge to heart transplantation over an extended period, up to 18 mo

- Cohort Study
- 281
- Same as above (HMII Study)
- Same as above (HMII Study)

Survival and transplantatio n rates were assessed at 18 mo.

- Pts were assessed for AEs throughout the study and for QoL, functional status, and organ function for 6 mo.
- 6 mo Mortality 18% (95% CI: 77-87%)
- 1 y Mortality 27% (95% CI: 66-80%)
- 18 Mo Mortality 28% (95% CI: 65-79%)

Enrollment 3/05-4/08 (38 mo); 18 mo follow-up

- 78% of LVAD pts reached primary outcome measure, either received a transplant, recovered cardiac function and underwent device explantation, or remained alive with ongoing LVAD support at 18-mo follow-up

**Bleeding requiring pRBCs Respiratory failure Local infection, non-LVAD Ventricular arrhythmias Sepsis Right HF requiring extended inotropic support**

| Ventilatory Efficiency and the Selection of Pts for Heart Transplantation, Ferreira AM, Circulation HF, 2010 | Case-control | N/A | Primary valve disease; Congenital heart disease; Planned coronary; revascularization; Planned cardiac surgery; Age <18 y; Primary pulmonary disease; Previous cardiac transplantation; Submaximal CPX (peak RER) | NYHA II-IV Death or heart transplant | Median flu 26 mo Ve/VCO2 slope <43, 1y survival 97% 3y survival 89.4% Ve/VCO2 slope >43 1y survival 77.8% 3y survival 55.1% | Ve/VCO2 slope <43, 1y survival: 95% CI: 95.4-98.6, y survival: 95% CI: 85.8-93.0 p<0.001 Ve/VCO2 slope >43 1 y survival: 95% CI: 71.3-84.3, 3 y survival: 95% CI: 45.2-65.0 | No VT vs VT: p<0.001, 95% CI 2.3-4.8 Prognostic classification p<0.001 |

To develop a prognostic model using FAR as a continuous variable that incorporates pts with an undetectable VT. Secondly, to determine the prognostic power of the FAR with that of VO2pk and the VE/VCO2 slope in pts with HF.

To assess whether Ve/VCO2 slope would identify individuals likely to benefit from heart transplant more accurately than current exercise criteria for listing.

Ve/VCO2 slope <43, 1 y survival 97% 3 y survival 89.4% Ve/VCO2 slope >43 1y survival 77.8% 3y survival 55.1%
The HF Survival Score outperforms the peak oxygen consumption for heart transplantation selection in the era of device therapy, Goda A, JHLT 2011 21093299 (311).

To evaluate peak VO2 and HFSS as prognostic tools in pts with and without CRT-D referred for heart transplant evaluation

Case-control

ACEI/ARB 80% b-blocker 64% (no device) v 76% (any device) 715

Systolic HF pt referred for heart transplant evaluation Excluded pts unable to exercise for any reason

mean NYHA class 2.82 (total), 2.7 (no device) vs 2.9 (any device)

Outcome events were defined as death, urgent transplantation (UNOS Status 1), or implantation of LVAD. Pts who underwent transplant as non-urgent (UNOS status 2) were censored alive on the date of the transplant.

1 y event-free survival with peak VO2 10.1-14 Total cohort: 77% CRT+/ICD: 84% ICD +/- CRT: 80% Any device: 80% 1 year event-free survival with peak VO2 < 10 Total cohort: 65% CRT+/ICD: 52% ICD +/- CRT: 59% Any device: 58%

N/A N/A HFSS significantly discriminates between the 3 risk strata across all device groups, whereas peak VO2 <10 only discriminates high risk from low/medium risk.

1y event-free survival, amongst CRT+/ICD pts low risk HFSS 90%, medium risk HFSS 72%, high risk HFSS 56%

FUNCTIONAL/QOL OUTCOME

Improvement in QoL in Pts with HF who Undergo Transplantation, Grady KL, 1996 8878757 (312)

To compare QoL of pts with HF at time of listing for a heart transplant with that 1 y after transplantation

Cohort

Post-transplant maintenance immunosuppression included cyclosporine, prednisone and azathioprine. Some received induction anti-T-cell therapy.

148 Underwent cardiac transplantation at Loyola University of Chicago Medical Center or University of Alabama at Birmingham

N/A N/A Symptoms, health perception, functional status, stress, coping, life satisfaction, and overall QoL as measured by 6 point-completed instruments. Demographic and clinical data from chart review.

N/A N/A Total symptom distress decreased after heart transplantation. Overall level of functional disability improved after heart transplantation, though remained low.

</tr>
</tbody>
</table>

### Inclusion Criteria
- WRF occurred in 152 cases (37%), 5±3 d after admission. Old age, DM, HTN and acute coronary syndromes increased the risk of WRF. Inhospital furosemide doses as well as discharge treatment were similar in WRF and no-WRF pts. Serum Crealevation was the strongest independent determinant of a longer hospital stay (p=0.001). AEs occurred in 156 pts (38%) during follow-up, with 23 deaths and 135 readmissions. Cox analysis showed that WRF, transient or not, was an independent predictor of the risk of death or readmission (HR: 1.74 95%CI: 1.14–2.68; p<0.01).

### Exclusion Criteria
- N/A

### Primary Endpoint
- Combined death

### Secondary Endpoint
- Combined death; first unscheduled readmission for HF Outcome during the 6 mo after discharge was determined by contacting the pts or their general practitioners by telephone.

### Endpoints
- Combined death; first unscheduled readmission for HF Outcome during the 6 mo after discharge was determined by contacting the pts or their general practitioners by telephone.

### Statistical Analysis (Results)
- Cox analysis showed that WRF, transient or not, was an independent predictor of the risk of death or readmission (HR: 1.74 95%CI: 1.14–2.68; p<0.01).

### Additional Notes
- A total of 63% of pts had any renal impairment, and 29% had moderate to severe impairment. After follow-up ≥1 y, 38% of pts with any renal impairment and 51% with moderate to severe impairment died vs 24% without. Adjusted all-cause mortality was increased with any impairment (aHR: 1.56; 95% CI: 1.53-1.60, p <0.001) and moderate to severe impairment (aHR: 2.31; 95% CI: 2.18-2.44, p<0.001). Mortality worsened incrementally across the range of renal function, with 15% (95% CI: 14%-17%) increased risk for every 0.5 mg/dL increase in Cr and 7% (95% CI: 4%-10%) increased risk for every 10 mL/min decrease in eGFR.

as main cause of symptoms development of complications or undergoing procedures which may cause a rise in Cr during the hospitalization

Cowie MR, 2006 16624834 (337)
To determine the prevalence and risk factors for WRF among pts hospitalized for decompensated HF and the association with subsequent rehospitalization and mortality. Observational 299 Age >20 y, documented history of chronic HF defined according to the ESC criteria; documented evidence of impaired LVFS, as demonstrated by an EF 40% on TTE or other imaging technique on the index admission or within the preceding 6 mo Pts with a planned discharge within 24 h of admission; an investigator-defined history of ACS or cardiogenic shock within 1 mo prior to the index admission; receiving a new prescription for potentially nephrotoxic drugs within 2 d prior to admission; severe aortic stenosis, valvular disease anticipated to require surgery within 6 mo, 'high output' cardiac failure, or those undergoing chronic renal replacement therapy or cancer chemotherapy All-cause mortality during the initial hospitalization and within 30+7 d and 180+7 d of the index hospitalization; date and cause of subsequent hospital re-admissions were also recorded. N/A 1/3 of pts (72 of 248 pts, 29% (95% CI: 26-32%)) developed WRF during hospitalization. The risk of WRF was independently associated with SCr levels on admission (OR: 3.02, 95% CI: 1.58-5.76), pulmonary edema OR: 3.35, 95% CI: 1.79-6.27, and a history of AF: OR 0.35; 95% CI: 0.18-0.67. Although the mortality of WRF pts was not increased significantly, the length of stay was 2 d longer [median 11 d (90% range (4-41) vs 9 d (4-34), p=0.006]. The rehospitalization rate was similar in both groups.

Komukai K, 2008 18577827 (338)
To investigate whether renal dysfunction is associated with rehospitalization for CHF after successful discharge Observational 109 pts Pts with CHF who had been admitted and followed up after discharge at the outpatient clinic were reviewed. CHF was diagnosed by ≥2 cardiologists on the basis of the Framingham criteria HF complicated by acute MI, undergoing or starting dialysis during the follow-up period, or undergoing cardiac surgery during the follow-up period Rehospitalization for HF after discharge N/A Pts with decreased renal function (estimated GFR on admission <45ml E/min.1 E1.73m2) were rehospitalized more frequently than were pts with preserved renal function (estimated GFR on admission ≥45). Pts with decreased renal function were older and had higher rates of anemia, WRF during hospitalization, and previous HF hospitalization. Independent predictors of rehospitalization for HF identified with multivariate analysis were age, previous hospitalization for HF, decreased renal function, and non-use of an ACEI or ARB.

Akhter MW, 2004 15464689 (339)
Evaluate the relation between elevated Scr at baseline, as well as WRF during hospitalization, and Secondary analysis of the VMAC trial 481 (215 had RI and 266 did not) Patients with dyspnea at rest caused by acute HF Length of hospitalization, 30 d readmission rate as well as 30-d and 6-mo mortality N/A Elevated baseline Cr was associated with length of hospital stay (median 6 vs 7 d, p=0.003). RI was associated with a 59% increase in 30-d readmissions (17% vs 27%, p=0.016). Higher Cr on admission was associated with both morbidity and mortality. All-cause mortality at 6 mo increased
Nohria A, 2008 18371557

Examine the ESCAPE database to assess the impact of renal dysfunction in patients with acute HF.

Secondary analysis of the ESCAPE trial

A total of 433 pts were enrolled at 26 sites

LVEF ≤30%, recent hospitalization or escalation of outpatient diuretic therapy, and SBP ≤125 mm Hg who were admitted to the hospital with at least 1 sign and 1 symptom of HF, despite adequate treatment with ACEIs and diuretics

Creatinine >3.5 mg/dL, the use of dobutamine/dopamine >3 μg/kg/min or milrinone before randomization, and requirement for early right heart catheterization.

D alive and out of the hospital for 6 mo after randomization

30-d mortality and length of stay

Baseline and discharge RI, but not WRF, were associated with an increased risk of death and death or rehospitalization. Among the hemodynamic parameters measured in pts randomized to the PAC arm (n=194), only right atrial pressure correlated weakly with baseline Scr (r=0.165; p=0.03). There was no correlation between baseline hemodynamics or change in hemodynamics and WRF. A PAC-guided strategy was associated with less average increase in Cr, but did not decrease the incidence of defined WRF during hospitalization or affect renal function after discharge relative to clinical assessment alone.

Owan et al., 2006 16679257

Whether the severity of renal dysfunction, the incidence of WRF or outcomes has changed over time (secular trends) in pts hospitalized for HF therapy.

Observational

6440

All consecutive HF pts admitted to Mayo Clinic hospitals in Rochester, MN, between January 1, 1987, and December 31, 2002

N/A

Change in the incidence of WRF or outcomes over time

N/A

The incidence of WRF, defined as an increase in Scr >0.3 mg/dL, increased slightly over the study period (p=0.01). Renal dysfunction and development of WRF were associated with mortality. When adjusted for the changes in baseline characteristics, later admission year was associated with lower 3-mo (aOR: 0.98 per y; 95% CI: 0.96–0.99; p=0.008) and overall mortality (HR: 0.99 per y; 95% CI 0.98–1.00; p=0.002).

Krumholz, 2000 10781761

To determine the incidence and identify factors associated with the development of worsening renal function in elderly patients with acute HF and to examine the impact of WRF on in-hospital and economic outcomes.

Retrospective

1,681 pts from 18 Connecticut hospitals

Age ≥65 y; discharge with HF without having clear precipitants for renal dysfunction

Pts <65 y of age; pts whose diagnosis could not be validated by medical record review, pts with severe aortic stenosis, or HF secondary to a medical illness (e.g., sepsis); major complications (stroke, acute MI shock, heart arrest, hypotension, pneumonia, and infection) or underwent a cardiac procedure requiring contrast (cardiac catheterization or angioplasty) or bypass

The outcome variable for the first phase of the study was worsening renal function, defined as in the ELITE study as an increase in SCR level during hospitalization of >0.3 mg/dL from admission. The principal endpoints for the 2nd phase of the study were inhospital mortality, length of stay and cost, 30-d mortality and readmission, and 6-mo mortality and readmission.

N/A

WRF occurred in 28% of the cohort and was associated with male gender, HTN, rates <basilar, pulse >100 beats/min, SBP >200 mm Hg, and admission Scr>1.5 mg/dL. Based on the number of these factors, a pt’s risk for developing WRF ranged between 16% (<1 factor) and 53% (≥5 factors). After adjusting for confounding effects, WRF was associated with a significantly longer length of stay by 2.3 d, higher inhospital cost by $1,758, and an increased risk of inhospital mortality (aOR:2.72; 95% CI:1.62-4.58).
| Forman, 2004 | To determine the prevalence of WRF among hospitalized HF pts, clinical predictors of WRF, and hospital outcomes associated with WRF. | Cohort (retrospective) | 1,004 | HF pts hospitalized between July 1, 1997, and June 30, 1998, at 11 academic medical centers. Pts were excluded if their hospitalizations were for an elective procedure (e.g., percutaneous transluminal coronary angioplasty, pacemaker, or cardioversion) or if their hospital length of stay was <2 d. Other exclusion criteria included severe aortic stenosis, anticipated cardiac transplantation, transfer from another inhospital setting, chronic dialysis, use of a LV assist device, high-output HF, age <20 y, concomitant use of an investigational product or device, and patients receiving chemotherapy. Subjects were also excluded if Cr values were not documented at admission. | The principal outcome was WRF, defined as an increase in SCr of >0.3 mg/dL (26.5 μmol/L) from admission, consistent with several previous investigations; hospital length of stay, inhospital mortality, and complications occurring after the rise in creatinine. Complications were defined as shock, MI, stroke, major infection/sepsis, clinically significant hypotension, and new onset AF with ventricular rates >100 beats/min. | N/A | Among 1,004 HF pts studied, WRF developed in 27%. In the majority of cases, WRF occurred within 3 d of admission. History of HF or DM, admission Cr ≥1.5 mg/dL (132.6 μmol/L), and SBP >160 mm Hg were independently associated with higher risk of WRF. A point score based on these characteristics and their RR ratios predicted those at risk for WRF. Hospital deaths (aRR: 7.5; 95% CI: 2.9-19.3), complications (aRR: 2.1; 95% CI: 1.5-3.0), and length of hospitalizations >10 d (aRR: 3.2; 95% CI: 2.2-4.9) were greater among pts with WRF. |
To investigate the relation between admission values and changes in BUN and eGFR and rate of death by 60 d after discharge

Retrospective OPTIME-CHF (multicenter, randomized, double-blind, placebo-controlled trial)

Pts >18 y who had known systolic HF and had been hospitalized for exacerbation of no more than 48 h earlier

Active myocardial ischemia within the past 3 mo, AF with poor ventricular rate control (>110/min), sustained ventricular tachycardia or ventricular fibrillation, baseline SBP <80 mm Hg or SCr level >3.0 mg/dL (265 µmol/L)

Total no. of d hospitalized for cardiovascular causes within 60 d of randomization. D lost to follow-up and 4 deceased were prospectively included in the primary endpoint to avoid bias toward a therapy with an increased death rate

N/A

Although both lower admission eGFR and higher admission BUN were associated with higher risk of death by 60 d after discharge, multivariable proportional-hazards analysis showed that BUN was a stronger predictor of death by 60 d than was eGFR.

Total no. of d hospitalized for exacerbation of no more than 48 h earlier

Baseline SBP <80 mm Hg or SCr level >3.0 mg/dL (265 µmol/L)

To investigate the relation between admission values and changes in BUN and eGFR and rate of death by 60 d after discharge, multivariable proportional-hazards analysis showed that BUN was a stronger predictor of death by 60 d than was eGFR. Indepedently of admission values, an increase of ≥10 mg/dL in BUN during hospitalization was associated with worse 60-d survival rate: BUN (per 5-mg/dL increase) had a HR: 1.08; 95% CI: 1.01-1.16. Although milrinone treatment led to a minor improvement in renal function by discharge, the 60-d death and readmission rates were similar between the milrinone and placebo groups.

Examine effects on mortality and rehospitalization of carvedilol use at discharge in pts hospitalized for HF and LVSD compared with outcomes in pts who are eligible for, but do not receive, beta blockers before discharge.

Registry 5791

OPTIMIZE-HF program enrolled 5791 pts admitted with HF, web-based registry at 91 hospitals participating with prespecified 60-90 d follow-up from March 2003 to December 2004.

N/A 2373 (87.2%) eligible to receive a beta blocker at discharge. Carvedilol prescribed in 1162 (49.0%). Discharge carvedilol associated with a significant reduction in mortality (HR: 0.46; p=0.0006) and mortality and rehospitalization (OR: 0.71, p=0.0175) compared to no predischarge beta blocker.

Ace-Inhibitors During and at Discharge of HF Hospitalization

Willenheimer R, van Veldhuisen DJ, Silke B et al. Effect on Survival and Hospitalization of Initiating Treatment for Chronic HF With Bisoprolol Followed by Enalapril, as Compared With the Opposite Sequence: Results of the Randomized CIBIS III. *Circulation* 2005;112:2426-35. 15143698 (186)

To determine whether the sequence of initiation of beta blockers or ACEI during hospitalization make a difference in outcomes.

RCT 101

Mild to moderate HF and LVEF ≤45%, who were not receiving ACEI, beta blocker, or ARB therapy randomized to open-label bisoprolol (target dose 10 mg QD; n=505) or enalapril (target dose 10 mg BID; n=505) for 6 mo, followed by their combination for 6 to 24 mo.

N/A Bisoprolol-first treatment noninferior to enalapril-first treatment (HR: 1.17). Primary end point in 178 pts allocated to bisoprolol-first treatment vs 186 allocated to enalapril-first treatment (HR: 0.94; 95% CI: 0.77-1.16). Bisoprolol-first treatment: 65 pts died, vs 73 with enalapril-first treatment (HR: 0.88; 95% CI: 0.63 to 1.22), and 151 vs 157 pts hospitalized (HR: 0.95; 95% CI: 0.76-1.19).

p=ns HR: 0.94  N/A

To evaluate the effect of developing and implementing CPGs on the quality of care given to pts receiving ACEI for systolic HF.

RCT

20 cardiology units in France (Experimental group (n=10) in each experimental unit, doctors were involved in drafting and implementing CPGs; those at control units were not.)

HF pts <75 y old Age >75 y Compliance with the CPG relating to ACEI dose on discharge higher in the experimental group (p=0.003).

Spironolactone During and at Discharge of HF Hospitalization

© American College of Cardiology Foundation and American Heart Association, Inc. 179
Hamaguchi S, Kinugawa S, Tsuchihashi-Makaya M et al. Spironolactone use at Discharge was Associated With Improved Survival in Hospitalized Pts With Systolic HF. Am Heart J 2010;160:1156-62. 21146672 (360)
Whether the discharge use of spironolactone is associated with better mortality and rehospitalization among hospitalized systolic HF pts.
Prospective cohort 946 Hospitalized HF pts with reduced LVEF <40%
N/A Spironolactone prescribed at discharge in 435 pts (46%).
Discharge use of spironolactone associated with reduction in death (HR: 0.612; p=0.020) and cardiac death (HR: 0.524; p=0.013).

Appropriateness of spironolactone prescription at discharge.
N/A 1502 pts prescribed spironolactone at discharge.
18% had hyperkalemia during hospitalization and 23% were discharged on concurrent potassium supplements. Although only 8% of pts with SCR >2.5 mg/dL, many with stage III (53.1%), stage IV (12.8%), or stage V (3.9%) chronic renal insufficiency.

Digoxin During and at Discharge of HF Hospitalization
To determine the effect of digoxin at discharge in pts hospitalized with HF.
Cohort 347 Hospitalized pts with HF.
Competing non-HF diagnoses HF hospitalizations (HR: 1.08; 95% CI: 0.77-1.50; p=0.66), total mortality (HR: 1.03; 95% CI: 0.78-1.35, p=0.85), or the combined end point of HF hospitalization and total mortality (HR: 1.11, 95% CI: 0.81-1.53, p=0.52) not different in pts treated with digoxin compared with those not treated with digoxin.

To determine the correlates of inappropriate digoxin use in older HF pts.
Cohort 603 Older hospitalized HF pts with documented LVEF and EKG.
N/A Digoxin use considered inappropriate if pts had preserved LVEF (≥40%) or if they had no AF. 376 pts (62%) discharged on digoxin, and 223 (37%) without indication for use. Of 132 pts without an indication and not already on digoxin, 38 (29%) initiated on it.

Adherence to Performance Measurements or Guidelines for Evidence Based Medication Use During Hospitalization
Krantz MJ, Ambardekar AV, Kaltenbach L, Hernandez AF, Heidenreich PA, Fonarow GC. Patterns and Predictors of Noncontraindicated Use of ACEI/ARBs. Registries (GTWG-HF) 9474 N/A Of those treated before hospitalization, continuation rates: 88.5% for ACEI/ARBs, 91.6% for beta blockers, and 71.9% for aldosterone-antagonists.

© American College of Cardiology Foundation and American Heart Association, Inc. 180
## Evidence-Based Medication Continuation Among Hospitalized HF Pts (from Get With the Guidelines-HF). Am J Cardiol 2011 June 15;107(12):1818-23. 21482418 (364)

Of pts untreated before admission, 87.4% started on ACEI/ARBs, 90.1% beta blockers and 25.2% on an aldosterone antagonist during hospitalization or at discharge. Admission therapy most strongly associated with discharge use (OR: 7.4, 6.0, and 20.9 for ACEI/ARBs, beta blockers, and aldosterone antagonists, respectively).

To develop and implement a program ensuring appropriate prescription of aspirin, statins, beta blockers, ACEI, and warfarin at hospital discharge.

Prospective cohort study of 57465 enrolled from 10 largest hospitals in the Utah-based Intermountain Health Care system. A nonrandomized / before-after study comparing pts hospitalized before (1996-1998) and after (1999-2002) implementation of a DMP.

Rate of prescription of each medication increased significantly to >90% (p<0.001). RR for death and readmission at 30 d decreased after DMP implementation; HRs for death and readmission: 0.81 (95% CI: 0.73-0.89) and 0.92 (95% CI: 0.87-0.99) (p=0.001 and p=0.017, respectively). At 1 y, risk for death still low (HR: 0.79; 95% CI: 0.75-0.84; p=0.001) while risk for readmission stabilized (HR: 0.94; 95% CI: 0.90-0.98; p=0.002).

AHA Scientific Statement for Treatment of Acute HF Syndromes

To characterize acute HF syndromes: from presentation, treatment, and disposition.

Recent Studies with Other Oral Medications for Treatment of Acute HF

To evaluate short-term effects of tolvaptan when added to standard therapy in pts hospitalized with HF.

RCT (EVEREST) 2048 trial A, 2085 (trial B) 4133 tolvaptan (30 mg/d), or matching placebo, within 48 h of admission. Subjects must have signs of extracellular volume expansion, defined as ≥2 of the following: a) JVD; b) pitting edema (>1+); or c) dyspnea. NYHA Class III or IV Women who will not adhere to the reproductive precautions as outlined in the ICF. Positive urine pregnancy test. Inability to provide written informed consent. Cardiac surgery within 60 d of potential study enrollment, excluding PCI. Planned revascularization procedures, EP device implantation, cardiac mechanical support implantation, cardiac transplantation, or other cardiac surgery within 30 d following study enrollment. Subjects who are on cardiac mechanical support. Hx of biventricular pacemaker placement

Tolvaptan had no effect on long-term mortality or HF-related morbidity. Mortality for tolvaptan vs placebo not different (HR: 0.98; 95% CI: 0.87-1.11; p=0.68). Composite of CV death or hospitalization for HF not different (HR: 1.04; 95% CI: 0.95-1.14; p=0.55). Secondary end points CV mortality, CV death or hospitalization, and worsening HF not different between tolvaptan and placebo. Tolvaptan significantly improved secondary end points of Day 1 pti-assessed dyspnea, Day 1 body weight, and Day 7 edema. In pts with hyponatremia, serum sodium levels significantly increased.

95% CI: 0.87-1.11; p=0.68

Secondary end points CV mortality, CV death or hospitalization, and worsening HF not different between tolvaptan and placebo. Tolvaptan significantly improved secondary end points of Day 1 pt-assessed dyspnea, Day 1 body weight, and Day 7 edema. In pts with hyponatremia, serum sodium levels significantly increased.

| 95% CI: 0.87-1.11; p=0.68 | HR: 0.98 | N/A |
valvular disease. Hypertrophic cardiomyopathy (obstructive or non-obstructive). CHF due to uncorrected thyroid disease, active myocarditis or known amyloid cardiomyopathy. Subjects with progressive or episodic neurological disease such as multiple sclerosis or Hx of multiple strokes. Hx of primary significant liver disease or acute hepatic failure, as defined by the investigator. Hx of poorly controlled DM. Morbid obesity, defined as >159 kg (or 350 lbs) or BMI >40. Supine systolic arterial blood pressure <90 mmHg. SCr >3.5 mg/dL or >309.4 mmol/L. Serum potassium >5.5 mEq/L or >5.5 mmol/L. Hgb <9 g/dL or <90 g/L. Hx of hypersensitivity and/or idiosyncratic reaction to benzazepine derivatives (such as benazapril). Hx of drug or medication abuse within the past y, or current alcohol abuse. Inability to take oral medications. Participation in another clinical drug or device trial within the past 30 d. Previous participation in this or any other tolvaptan clinical trial.

AF indicates atrial fibrillation; AFFIRM, Atrial Fibrillation Follow-up Investigation of Rhythm Management; CHF, congestive heart failure; CrCl, creatinine clearance; CV, cardiovascular; HR, hazard ratio; ITT, intent-to-treat; LV, left ventricular; LVEF, left ventricular ejection fraction; NYHA, New York Heart Association; Pts, patients; RCT, randomized control trial; RE-LY, randomized evaluation of long-term anticoagulant therapy trial; ROCKET-AF, Rivaroxaban Once Daily Oral Direct Factor Xa Inhibitor Compared with Vitamin K Antagonism for Prevention of Stroke and Embolism Trial in Atrial Fibrillation; RR, relative risk; and TIA, transient ischemic attack;
| CM in a heterogeneous CHF population: a RCT | Test the effect of CHF case management with the following 4 components: 1. early discharge planning, 2. pt and family CHF education, 3. 12 wk of telephone f/u, and, 4. promotion of optimal CHF medications | RCT | 287 | Primary or secondary diagnosis of CHF, LVD <40%, or radiologic evidence of pulmonary edema for which they underwent diuresis; had to be at risk for early readmission | Discharge to a long-term care facility, planned cardiac surgery, cognitive impairment, anticipated survival of <3 mo, and long-term hemodialysis | 90-d readmission rate | Adherence to treatment plan and pt satisfaction | There was no difference between the 2 groups in 90-d re-admission rates (both were 37%, p>0.99). The intervention group showed greater adherence to most aspects of the treatment plan (p<0.01) and pts in this group reported greater pt satisfaction (p<0.01). Subgroup of pts who live in area and received care from local cardiology decreased CHF readmission rate (2%vs. 14%; p=0.03). Study was not blinded, adherence was assessed via pt self-report; and no consistent method for NYHA classification. | The intervention did not increase costs and study showed that strong working relationships between the CM and cardiologists decreased CHF hospital readmission rates. |

| CM for pts with chronic systolic HF in primary care: the HICMan exploratory RCT. | To compare CM vs. usual care on pt outcomes. | RCT | 197 | Adults with LVEF ≤45% | HRQoL, HF self-care, and pt-reported quality of care. | Nonsignificant between group differences for the KCCQ overall summary scores favored CM: 1.7 (95%CI: -3.0-6.4; p=0.477). Heart failure self-care behavior scores were significant group differences favoring CM: -3.6 (95%CI: -5.7–1.6; Cohen's d 0.55; p=0.001). Significant between group differences quality of chronic illness care (0.5; 95% CI: 0.3-0.7; p=0.000) and behavior counseling (0.5; 95% CI: 0.3-0.8; p=0.000), with moderate effect sizes (Cohen's d 0.7 for each summary score). Small, unblended sample of patients from a non-representative sample of physicians. | The intervention failed to improve overall QoL, though showed significant improvements in pt-reported quality of care and chronic HF self-care. |

| Impact of a specialized outpatient HF follow-up program on hospitalization frequency and functional status of pts with AHF. | To evaluate the impact of a specialized outpatient HF follow-up program | Retrospective | 147 | Not reported | Not reported | Frequency and duration of hospitalization for HF and functional status | Significant improvement in NYHA class during the mean follow-up period: 55% of the pts were in class III, 37% in class II, 5% in class I and 3% in class IV (p<0.0001). Hospitalizations for acute decompensation of HF decreased: 87 at baseline vs. 25 (p<0.0001) Small retrospective study | No significant differences were found in the proportion of pts on therapeutic drugs or in mean duration of hospitalization |
Outpatient medical and nurse management program in pts with chronic HF in a large territorial area in Piedmont, 4 y of follow-up. 4

16444925 (377)

To evaluate an outpatient management program for pts with chronic HF

Prospective trial

Adults with chronic HF in the Piedmont region of Italy.

Hospitalization and ED admissions in the 12 mo before the 1st evaluation and every y after referral

MLWHF, NYHA functional class, pharmacological therapies at the referral time and at the end of follow-up.

EF improved from 31 +/- 10 to 36 +/- 12%. ED admissions and hospitalizations decreased (p < 0.001). NYHA classes I-II improved from 65.5 to 87.7% and NYHA classes III-IV were reduced from 34.5 to 12.3%. MLWHF score decreased from 25 to 21.9. Pts treated with ACEI + ARB increased from 91 to 96%, beta blockers from 35.2 to 69%, potassium sparing drugs increased from 54 to 64%.

Small trial, not generalizable to populations outside of Italy.

Showed a decrease in the number of hospitalizations and improvement in NYHA functional class and adherence to medical therapy. These results kept constant over time in the subsequent 4 y.

ACEI indicates angiotensin-converting-enzyme inhibitor; AHF, acute heart failure; ARB, angiotensin receptor blockers; CHF, congestive heart failure; CM, case management; ED, emergency department; EF, ejection fraction; HF, heart failure; HRQoL, health related quality of life; KCCQ, LVD, left ventricular dysfunction; MLHF, Minnesota Living with Heart Failure; NYHA, pts, patients; and QoL, quality of life.

This table represents all healthcare relationships of committee members with industry and other entities that were reported by authors, including those not deemed to be relevant to this document, at the time this document was under development. The table does not necessarily reflect relationships with industry at the time of publication. A person is deemed to have a significant interest in a business if the interest represents ownership of ≥5% of the voting stock or share of the business entity, or ownership of ≥$10,000 of the fair market value of the business entity; or if funds received by the person from the business entity exceed 5% of the person’s gross income for the previous year. Relationships that exist with no financial benefit are also included for the purpose of transparency. Relationships in this table are modest unless otherwise noted. Please refer to [http://www.cardiosource.org/Science-And-Quality/Practice-Guidelines-and-Quality-Standards/Relationships-With-Industry-Policy.aspx](http://www.cardiosource.org/Science-And-Quality/Practice-Guidelines-and-Quality-Standards/Relationships-With-Industry-Policy.aspx) for definitions of disclosure categories or additional information about the ACCF/AHA Disclosure Policy for Writing Committees.

*Indicates significant relationship.
†No financial benefit.

ACC indicates American College of Cardiology; AHA, American Heart Association; AHEAD, Action For Health in Diabetes; AHRQ, Agency for Healthcare Research & Quality; ALECARDIO, Cardiovascular Outcomes Study to Evaluate the Potential of Aleglitazar to Reduce Cardiovascular Risk in Patients With a Recent Acute Coronary Syndrome Event and Type 2 Diabetes Mellitus; ALTITUDE, Aliskiren Trial in Type 2 Diabetes Using Cardio-Renal Endpoints; ASCEND-HF, Acute Study of Clinical Effectiveness of Nesiritide in Decompensated Heart Failure; CHAMPION, CardioMEMS Heart Sensor Allows Monitoring of Pressure to Improve Outcomes in NYHA Class III Patients; DCRI, Department of Clinical Research Informatics; DSMB, Data Safety Monitoring Board; EP, electrophysiology; EXSCEL, Exenatide Study of Cardiovascular Event Lowering; GWTG, Get With The Guidelines; HF, heart failure; HFSA, Heart Failure Society of America; IMPROVE HF, Registry to Improve the Use of Evidence-Based Heart Failure Therapies in the Outpatient Setting; INTERMACS, Interagency Registry for Mechanically Assisted Circulatory Support; NHLBI, National Heart, Lung, and Blood Institute; NIDDK, National Institute of Diabetes and Digestive and Kidney Diseases; NIH, National Institute of Health; NYU, New York University; PARADIGM-HF, Prospective Comparison of ARNI With ACEI to Determine Impact on Global Mortality and Morbidity in Patients With Heart Failure; PRIDE, Prolonging Remission in Depressed Elderly; SUNY, State University of New York; TECOS, Trial Evaluating Cardiovascular Outcomes with Sitagliptin in Patients with Type 2 Diabetes; UCLA, University of California, Los Angeles; UNOS, United Network for Organ Sharing; and VA, veterans affairs.
