Hemodynamic Effects of Isoproterenol Infusion in Patients with Normal and Diseased Mitral Valves

By Robert E. Whalen, M.D., Allan I. Cohen, M.D., Robert G. Sumner, M.D., and Henry D. McIntosh, M.D.

Hemodynamic effects of isoproterenol infusion have been studied in man by several groups. These observations, however, have been limited to events occurring in the right heart and lesser circulation. The purpose of this paper is to report the hemodynamic alterations associated with isoproterenol infusion that occur in the left heart of patients with normal and diseased mitral valves.

Materials and Methods

Twenty-six adult patients were studied by combined right and left heart catheterization to define or further to quantitate valvular defects suspected on clinical grounds. Right heart catheterization was accomplished in the usual fashion from an antecubital vein and the left heart was studied by combined transseptal left atrial and retrograde left ventricular catheterization.

By use of these methods the presence or absence of a diastolic gradient across the mitral valve could be determined from the simultaneous left atrial and left ventricular pressure pulses. To determine the presence of mitral insufficiency, 1.5 ml. of a 500 mg. per cent solution of indocyanine dye was injected into the left ventricle while blood was being continuously drawn from the left atrium through a densitometer coupled to a photographic recorder. A deflection that occurred within 6 seconds of injection was considered evidence of mitral insufficiency (fig. 1). This interval represented transit time of the dye from catheter to the left ventricle, reflux of dye into the left atrium, and transit time of blood containing dye from left atrium to the densitometer. In this and other laboratories this method of detecting mitral insufficiency has proved more reliable than analysis of the left atrial pulse contour. In the majority of cases the presence or absence of insufficiency was confirmed by cineangioeardiograms in which contrast medium was injected into the left ventricle.

On the basis of these observations the 26 patients were divided into four groups:

Group I (patients with normal mitral valves) consisted of five patients in whom there was no mitral diastolic gradient and no early appearance of indocyanine dye in the left atrium after left ventricular injection. This group included two patients with functional murmurs, one with mild pulmonary hypertension of unknown etiology and two patients with mild aortic insufficiency.

Group II (patients with pure mitral stenosis) consisted of 11 patients in whom there was a mitral diastolic gradient throughout diastole but no early appearance of indocyanine dye in the left atrium after left ventricular injection.

Group III (patients with pure mitral insufficiency) consisted of five patients in whom there was no mitral diastolic gradient but who demonstrated early appearance of indocyanine dye in the left atrium following left ventricular injection.

Group IV (patients with combined mitral stenosis and insufficiency) consisted of five patients in whom there was a mitral diastolic gradient throughout diastole and early appearance of indocyanine dye in the left atrium after left ventricular injection.

All pressures were measured with Statham strain gages (P 23D) coupled to a photographic recorder. The mean mitral diastolic gradient was determined by simultaneously recording the left ventricular and left atrial pressures with equisensitive gages at a paper speed of 100 mm. per second and time lines of .04 second (fig. 2). Both pressure pulses were obtained at high sensitivities (1 mm. Hg = 3 to 12 mm. recorder deflection). The magnitude of the gradient was determined by measuring the distance between the pressure tracings.
HEMODYNAMIC EFFECTS OF ISOPROTERENOL

Figure 1

Demonstrates indicator-dilution curves inscribed when indicator is injected into the left ventricle while blood is being continuously sampled from the left atrium. There is no early appearance of indicator in the top curve, which was obtained from a patient with a normal mitral valve. Early appearance of indicator is seen in the bottom curve, which was obtained from a patient with mitral insufficiency.

Figure 2

A section from the record of a patient with pure mitral stenosis. Both the left atrial and left ventricular pressure pulses are recorded at high sensitivities to enable more accurate measurement of the diastolic gradient, which is indicated by the cross-hatched section.

The cardiac output was estimated by a previously described modification of the Hamilton-Stewart method. Indocyanine dye was injected in the pulmonary artery, and blood was sampled from a peripheral artery through a densitometer coupled to a multichannel photographic recorder that inscribed an indicator-dilution curve. The stroke volume was calculated by dividing the cardiac output by the heart rate recorded during inscription of the dilution curve.

The total peripheral resistance was expressed in units and calculated from the formula:

\[
\text{Total peripheral resistance} = \frac{\text{Mean arterial pressure (mm. Hg)}}{\text{Cardiac output (L./min.)}}
\]

The pulmonary vascular resistance was also expressed in units and calculated from the formula:

\[
\text{Pulmonary vascular resistance} = \frac{\text{Mean pulmonary artery pressure} - \text{mean left atrial pressure (mm. Hg)}}{\text{Cardiac output (L./min.)}}
\]

In cases of pure mitral stenosis the mitral valve area was calculated by a modification of the Gorlin formula:

\[
\text{Mitral valve area} = \frac{\text{Diastolic filling period/minute}}{31 \sqrt{\text{Mean mitral diastolic gradient}}}
\]

In cases of combined mitral stenosis and insufficiency, the modified Gorlin formula was used:

\[
\text{Mitral valve area} = \frac{\text{Diastolic filling period/minute}}{31 \sqrt{\text{Mean mitral diastolic gradient}}}
\]

The following abbreviations apply to tables 1 to 4: PA, pulmonary artery; LA, left atrial; LVED, left ventricular end-diastole; C, control; I, infusion.

Results

The results are listed in tables 1 to 4 and figures 3 and 4. When the average per cent change from control values are reviewed in group I (normal mitral valves) it is noted that the volume tended to rise, while the mean pulmonary arterial pressure, mean left atrial pressure, mean peripheral resistance, and total peripheral resistance fell. The average per cent change from control values was +25.

The following abbreviations apply to tables 1 to 4: PA, pulmonary artery; LA, left atrial; LVED, left ventricular end-diastole; C, control; I, infusion.

Diagram

Figure 3

Demonstrates the average per cent change from control. The diagram shows the effects of isoproterenol infusion on heart rate, cardiac output, stroke volume, mean left atrial (LA) pressure, and left ventricular (LVDP) pressure. The data are compared to normal mitral values. The diagram indicates that isoproterenol increased heart rate, cardiac output, and stroke volume. Mean left atrial pressure and left ventricular pressure decreased. Mean pulmonary arterial pressure and mean peripheral resistance decreased. Total peripheral resistance fell.

Note that patients with pure mitral stenosis had no change (0) in stroke volume.

HEMODYNAMIC CHANGES INDUCED BY ISOPROTERENOL INFUSION

![Graph showing hemodynamic changes](image)

Demonstrates the average per cent change from control values of mean pulmonary artery (PA) pressure, pulmonary vascular resistance, mean arterial pressure, and total peripheral resistance in patients with normal mitral valves, pure mitral stenosis (M.S.), pure mitral insufficiency (M.I.), and combined mitral stenosis and insufficiency. Note that patients with combined mitral stenosis and insufficiency showed no (0) change in mean pulmonary artery pressure.

In group II (pure mitral stenosis) the heart rate, cardiac output, mean pulmonary artery pressure, and mean left atrial pressure rose. The left ventricular end-diastolic pressure, total peripheral resistance, and pulmonary vascular resistance fell, whereas there was little change in the stroke volume, arterial pressure, or diastolic filling period per minute. The mean mitral diastolic gradient rose in all instances. This increase was due not only to an increase in left atrial pressure, but also to a decrease in left ventricular end-diastolic pressure. As would be expected, the calculated mitral valve area changed little.

In group III (pure mitral insufficiency) there was an increase in heart rate, cardiac output, and stroke volume. There tended to be a fall in mean pulmonary artery pressure, mean left atrial pressure, left ventricular end-diastolic pressure, pulmonary vascular resistance, and total peripheral resistance. The
mean arterial pressure and diastolic filling period per minute were essentially unchanged. Thus groups I and III responded in the same fashion.

In group IV (combined mitral stenosis and insufficiency) there was an increase in heart rate, cardiac output, mean left atrial pressure, and mean mitral diastolic gradient. The left ventricular end-diastolic pressure, pulmonary vascular resistance, and total peripheral resistance fell. There was little change in the stroke volume, mean pulmonary arterial pressure, mean arterial pressure, and diastolic filling period per minute.

Discussion

Isoproterenol infusion leads to certain consistent hemodynamic responses regardless of the status of the mitral valve. Figures 3 and 4 demonstrate that there was an increase in heart rate and cardiac output while there was a fall in pulmonary vascular resistance and total peripheral resistance in all four groups of patients. These results are consistent with data obtained from right heart catheterization in normal subjects and patients with or without valvular disease.1, 2 Left ventricular end-diastolic pressure also fell in all four groups.

A comparison of patients with normal mitral valves (group I) and those with pure mitral insufficiency (group III) indicates that the presence of mitral insufficiency does not alter the direction of hemodynamic responses. The presence of mitral stenosis, however, significantly altered the hemodynamic response to isoproterenol. Unlike patients with normal or insufficient valves, patients with mitral stenosis responded with a significant increase in left atrial mean pressure and mean pulmonary artery pressure. Heart rate increased proportionately to cardiac output; therefore, the calculated stroke volume was unchanged.

Patients with combined mitral stenosis and insufficiency (group IV) formed a heterogeneous group consisting of some patients with predominant mitral stenosis and others with predominant insufficiency. Analysis of the data would suggest that the presence of insufficiency served to cancel some of the effects
stemming from stenosis. Thus, while the stroke volume rose in this group, it did not rise as high as that of the normal or the pure mitral insufficiency group. Although the mean left atrial pressure rose in this group, it did not reach the heights noted in patients with pure mitral stenosis. The lack of any increase in mean pulmonary artery pressure lies midway between the increase noted in patients with mitral stenosis and the decrease noted in patients with normal or insufficient valves.

Isoproterenol has a variety of hemodynamic effects. The increase in heart rate seen in this study is a manifestation of its chronotropic activity.\textsuperscript{8, 9} The increased cardiac output and stroke volume are consistent with its known inotropic activity.\textsuperscript{8-10} The decrease in the pulmonary vascular resistance and total peripheral resistance are manifestations of the drug’s ability to produce arterial dilatation in the pulmonary and systemic arterial circuits.\textsuperscript{8-11} The decrease in mean left atrial pressure seen in patients with normal mitral valves is consistent with earlier observations on the response of right atrial pressure to this drug.

Mitral stenosis produces marked alterations in the hemodynamic response to this drug. Whenever the resting left atrioventricular gradient is elevated, persistent increase in cardiac output above the resting level can be achieved only by a further increase in gradient. As the flow across the valve varies with the square root of the gradient, small changes in flow are associated with easily measured increases in the left atrioventricular gradient. The inotropic action of the drug leads to an increase in flow into the lungs and left atrium, but the stenotic valve prevents an equal increase in output of the left ventricle until the left atrioventricular gradient reaches its new level. Despite the fall in pulmonary vascular resistance, the pulmonary artery pressure rises, because of an increase in volume in the lesser circulation. The new gradient is achieved by a decrease in left ventricular end-diastolic pressure and an increase in left atrial pressure.

In patients with unobstructed mitral valves the fall in mean left atrial pressure is a reflection of the fall in left ventricular end-diastolic pressure, as the left atrium and ventricle become a common chamber in diastole. There are a number of mechanisms that would account for the drug-induced fall in mean left atrial and left ventricular end-diastolic pressure in patients with unobstructed mitral valves. Among these could be included a redistribution of blood away from the central reservoir, a decrease in central venous tone, and an increase in atrial and ventricular distensibility. The observation that cardiac output and mean left atrial pressure rise while left ventricular end-diastolic pressure falls in patients with mitral stenosis indicates that redistribution of blood away from the central venous reservoir and a decrease in central venous tone are not adequate explanations for the fall in left atrial and left ventricular end-diastolic pressure seen in patients with unobstructed mitral valves. This observation suggests that isoproterenol may have a direct effect on the distensibility of the left ventricle. Although the effect of isoproterenol on ventricular distensibility has not been investigated, epinephrine, a closely related compound, is reported to increase ventricular distensibility\textsuperscript{12} in dogs.

There are several alternate explanations for the findings in patients with mitral stenosis. Since the diastolic filling period changed little during drug infusion, the increase in left atrial pressure and the mean diastolic gradient cannot be attributed to the chronotropic actions of the drug. Since the left atrial pressure rose in all patients with mitral stenosis, regardless of the presence of normal sinus rhythm or atrial fibrillation, it seems unlikely that the drug’s inotropic action on the left atrium played a critical role. Furthermore, enhanced left atrial contraction would be expected to lead to an increased stroke volume, which did not occur in the mitral stenosis group.

**Summary**

Hemodynamic effects of isoproterenol infusion were studied in 26 patients with and...
without mitral valve disease undergoing combined right and left heart catheterization. The heart rate and cardiac output rose while the left ventricular end-diastolic pressure, pulmonary vascular resistance, and total peripheral resistance fell, regardless of the status of the mitral valve. Infusion produced little change in the mean arterial blood pressure and the diastolic filling period per minute.

While the mean left atrial and pulmonary artery pressures fell in patients with normal or insufficient valves, these pressures rose in patients with mitral stenosis. Stroke volume tended to rise in all patients but those with mitral stenosis. In patients with combined mitral stenosis and insufficiency the insufficiency appeared to modify the hemodynamic response associated with mitral stenosis.

The presence of a lowered end-diastolic pressure in the left ventricle and an increased pressure in the left atrium in patients with stenosis suggests that isoproterenol has a direct or reflex effect on the left ventricle during diastole.
