Surgical treatment of pulmonary stenosis has advanced to the point where a choice of several operative technics is available. This study constitutes a comparative review of the late recatheterization results in the open versus closed method of pulmonary valvuloplasty.

Doyen reported an unsuccessful attempt to relieve pulmonary stenosis by transventricular valvulotomy in 1913.1 In 1948, Sellors reported a successful transventricular valvulotomy, and Brock reported three successful cases of pulmonary valvulotomy.3 The transventricular valvulotomy, commonly called the Brock procedure, has been used extensively. Varco introduced pulmonary valvulotomy under direct vision by a transarterial approach, inflow occlusion, and normothermia.4 Swan, combining hypothermia and inflow occlusion, increased the length of time available in correcting valvular stenosis by direct vision. With total cardiopulmonary bypass, anatomically precise valvulotomy, deliberate infundibular resection when necessary, and repair of associated defects can be done.

There are several reports of disappointing results following closed procedures for pulmonary stenosis because of failure to relieve the obstruction.5-11 In 1956 we reported the preoperative and postoperative right ventricular systolic pressures in 20 patients who had closed valvulotomy for pulmonary stenosis.9 The purpose of this study is to compare the results in our previous report with 25 patients all of whom have been catheterized postoperatively and who have had correction of pulmonary stenosis by open technics with cardiopulmonary bypass.

Materials and Methods

Twenty-five consecutive patients have had follow-up catheterizations after surgical treatment for pulmonary stenosis by the open technic. Their anatomic types are listed in table 1. The ventricular septum was intact in all of these patients.

The age ranged from 4 to 39 years at the time of surgery, the diagnoses, valvular, infundibular, or combined stenosis are postoperative. Resection of significantly hypertrophied infundibular areas was done in all cases designated as having infundibular stenosis; two patients required an outflow patch. A tight fibromuscular ring was present in the two patients with isolated infundibular stenosis.

Only three of the patients had repair of the atrial septal defects, the remainder of those designated as atrial septal defect were probe-patent foramen ovale defects. Postoperative cardiac catheterization was done at varying intervals from 9 to 36 months. The average period between surgery and follow-up catheterization

Public Health Service; Maria and Joseph Gales Ramsay III Cardiovascular Fund; Benefactors of Cardiovascular Research Fund; and Max Baer Heart Fund of Fraternal Order of Eagles.
was 13 months. Right ventricular pressures and pulmonary artery pressures were recorded. With the exception of four patients, right ventricular pressures were also taken in the operating room after repair of the stenosis. History, physical examination, electrocardiography, and cardiac fluoroscopy were also obtained.

**Results**

There was clinical improvement in all of the patients. Those who were symptomatic preoperatively demonstrated an increased exercise tolerance and less fatigue at the time of follow-up. None of the patients had symptoms related to cardiac decompensation. Five of the patients who had a distinctly palpable thrill preoperatively had a notable decrease in its intensity. There was a lessening in the intensity of systolic murmur in all of the patients. Two patients developed an early diastolic murmur over the left sternal border, which was consistent with pulmonary valve incompetence. These two patients were asymptomatic and right ventricular systolic pressures were 30 and 38 mm. Hg, with a diastolic range from 0 to +4 mm. Hg.

Changes in heart size and pulmonary vascularity as determined by roentgenography were not striking. Eighteen of the patients showed a decrease in the amplitude of the R wave in V1. The level of the right ventricular systolic pressure correlated quite well with these R-wave changes.

The right ventricular systolic pressure showed a significant decrease in all of the patients. Consistent with the experience of others,12 the right ventricular systolic pressure taken in the late postoperative period showed significant reductions from the readings in the operating room. In addition, three of the patients did not have a satisfactory reduction in the right ventricular pressure at the time of operation but later had significantly lower pressures (fig. 1). The average right ventricular systolic pressure before operation in the group done by open technic (table 2) was 124 mm. Hg, following surgery the

Correction of pulmonary stenosis by open operation.

_Circulation, Volume XXXII, August 1965_
average value was 35 mm. Hg, a mean decrease of 89 mm. Hg. In a previously studied 20 patients who had Brock-type closed valvulotomy, the average decrease in the right ventricular systolic pressure was 60 mm. Hg. Five of the patients with closed transventricular valvulotomy did not have a decrease in the pulmonary valve gradient, but all of those done by the open technic had a favorable change in their right ventricular pressures.

Discussion

These studies indicate that the open operation under direct vision has given significantly superior physiologic results when compared to closed or blind transventricular valvulotomy. Moreover, the direct vision operation makes it possible to open the stenotic valve with incisions precisely placed in the anatomic commissures when these are present, as they often are. A greatly lessened incidence of pulmonary valvular incompetence is thereby achieved when comparison is made with patients having closed or blind transventricular procedures. All of these open operations were done with use of the pump oxygenator.

Open pulmonary valvulotomies can readily be done under inflow stasis without bypass. We have had considerable experience with this technic in the past, but have abandoned it in favor of the open operation with bypass for several important reasons. The one exception to the above statement is emergency or urgent valvulotomies in newborn or neonatal infants with pulmonary atresia or severe stenosis where palliation rather than cure is the immediate goal.

The open bypass operation will yield a lower mortality and a higher percentage of postoperatively hemodynamically normal or near normal patients.

Whereas perfection in the preoperative diagnosis is the goal of all, it obviously cannot be reached in all cases. The open bypass approach allows the surgeon to ascertain and deal with these unanticipated findings safely and definitively. Moreover, even in the uncomplicated case operation under inflow stasis at normothermia or moderate hypothermia places such a premium on these few minutes (4 to 5 minutes maximum) that the need to hurry may result in less adequate valvuloplasties with the added risk that a technical mishap such as a tear in the pulmonary artery may result in death from hemorrhage. Lastly, the use of disposable pump oxygen-

LATE RESPONSE TO CORRECTION OF PULMONARY STENOSIS

ators14–16 and a non-blood prime17–19 adds little if any complexity to the bypass operation. There is little doubt that the delayed progressive decrease in right ventricular systolic pressure which follows successful valvulotomy is the result of a regression of secondary infundibular hypertrophy. However, true organic infundibular obstruction may coexist with valvular stenosis; in these patients it is essential to resect the infundibular obstruction as well as to carry out valvuloplasty. Moreover, with the more severe degrees of combined

Figure 3

J.T., No. 941009. Interpretation was valcular stenosis with normal infundibulum, note the relaxation in diastole (center). However, at operation the infundibulum appeared to show considerable tubular narrowing about 3 cm, long and therefore both valvulotomy and infundibular resection were done. Preoperative R.V. pressures: high 84/3, low 90/6. Postoperative R.V. pressure at recatheterization was 29/9. This type of infundibular hypertrophy was definitely secondary to valcular stenosis, and valvulotomy alone might have been adequate.

Figure 4

S.S., No. 901490. Combined valcular and organic infundibular stenosis. The constricted infundibulum remains rigid throughout the cardiac cycle. Note the constant nature of the large filling defect in the right ventricular outflow tract (representing severe organic infundibular obstruction) during both systole and diastole. Preoperative pressure in the R.V. was 215/15, the postoperative recatheterization pressure in the R.V. was 45/25. An outflow roof was also required. Valvulotomy without infundibular resection in this situation would likely be lethal.
valvular stenosis and infundibular hypertrophy it is essential to resect the infundibular element at the same time as valvuloplasty or the patient may not survive the immediate postoperative period. Early in our experience, two patients were encountered with right ventricular pressures above 200 mm. Hg. Valvulotomy without infundibular resection resulted in no fall in the right ventricular pressures recorded in the operating room, and both patients succumbed in the immediate postoperative period due to right heart failure with low cardiac output.

We have found preoperative selective right ventriculography to be essential in determining whether infundibular resection will be necessary (figs. 2 to 6), since it has proved considerably more accurate than observations made at operation, even when the heart was open. Any patient with questionable evidence supporting the diagnosis of infundibular obstruction, should be operated upon with cardiopulmonary bypass. Careful evaluation of preoperative angiocardiorams and the pressure determinations will usually provide adequate criteria for indicating preoperatively which patients need ventriculotomy and infundibular resection, but not invariably (fig. 3).

From the fatal result in the two patients with markedly elevated pressures that did not recede some immediately after valvulotomy, we have learned that if the preoperative level is above 140 to 150 mm. Hg, one should have an immediate significant drop (at least 1/3 to 1/2 reduction) in right ventricular systolic pressure on the operating table. If valvulotomy alone does not accomplish this goal, then infundibular resection with or without an outflow patch is necessary. This modus operandi has reduced operative risk to under 1 per cent.

**Summary**

A group of 25 patients was studied by cardiac catheterization before and after open operation for isolated pulmonary stenosis by direct vision with use of cardiopulmonary bypass. Organic infundibular obstruction, when present, was resected. The hypertrophied infundibulum, when it constitutes a severe obstruction, must also be resected. The average right ventricular systolic pressure preoperatively was 124 mm. Hg and postoperatively it was 35 mm. Hg.

The average gradient across the pulmonary valve preoperatively was 99 mm. Hg and postoperatively it was 17 mm. Hg, a mean decrease of 82 mm. Hg.

**Figure 5**

N.C., No. 992609. Severe isolated infundibular stenosis 4 to 5 cm. below a normal pulmonary valve. A 4-mm. diameter orifice was increased to 2 cm. by muscular resection together with an outflow roof of Teflon (17918) for reconstruction. The lateral views did not show the area of obstruction as well as the posteroanterior shown here. Preoperative R.V. pressure was 200/0 and dropped to 35/5 in the operating room immediately after correction.
The long-term hemodynamic response was distinctly superior in this group of patients operated upon under total bypass when compared with a similar series operated upon by us with a closed transventricular approach.

The specific diagnosis of lesions causing obstruction to the outflow of the right ventricle is particularly crucial in selecting an operative approach if open operation by inflow stasis is utilized.

Careful review of the selective right ventriculograms is an excellent preoperative guide in determining whether infundibular obstruction is present and hemodynamically significant.

Patients having severe valvular stenosis, with right ventricular pressures above 140 to 150 mm Hg should have an immediate one-third to one-half decrease in their right ventricular systolic pressures at the time of surgery, or infundibular resection should be done to reduce postoperative mortality.

The Pulmonary Circulation. Michael Servetus—1511-1553

"... It is not said that the divine spirit is principally in the walls of the heart, or in the body of the brain or of the liver, but in the blood, as is taught by God Himself in Gen. 9, Levit. 8, Deut. 12.

"In this matter there must first be understood the substantial generation of the vital spirit which is composed of a very subtle blood nourished by the inspired air. The vital spirit had its origin in the left ventricle of the heart, and the lungs assist greatly in its generation. It is a rarefied spirit, elaborated by the force of heat, reddish-yellow (flavo) and of fiery potency, so that it is a kind of clear vapor from very pure blood, containing in itself the substance of water, air, and fire. It is generated in the lungs from a mixture of inspired air with elaborated, subtle blood which the right ventricle of the heart communicates to the left. However, this communication is made not through the middle wall of the heart, as is commonly believed, but by a very ingenious arrangement the subtle blood is urged forward by a long course through the lungs; it is elaborated by the lungs, becomes reddish-yellow and is poured from the pulmonary artery into the pulmonary vein. Then in the pulmonary vein it is mixed with inspired air and through expiration it is cleaned of its sooty vapors. Thus finally the whole mixture, suitably prepared for the production of the vital spirit, is drawn onward to the left ventricle of the heart by diastole."—André CourNAnd, M.D. Circulation of the Blood.
