Observations on Changing Hemodynamics in Tricuspid Atresia Without Associated Transposition of the Great Vessels

By Marian E. Gallaher, M.D., and Donald C. Fyler, M.D.

SUMMARY
Three patients are discussed who, in early infancy, presented with mild cyanosis, cardiac decompensation, failure to thrive, and pulmonary congestion. These manifestations were associated with tricuspid atresia without transposition of the great vessels. The clinical course of these children, who in varying periods of time became progressively more cyanotic, with hearts becoming smaller, and with decreasing pulmonary blood flow, is unique. Cardiac catheterization and angiocardiographic studies were obtained at each end of the clinical spectrum in all of the children. Although a closing ventricular septal defect is thought to be the cause of the decreasing pulmonary flow, the studies were not conclusive. In all three patients, palliative systemic venous-to-pulmonary arterial anastomosis (Glenn procedure) relieved the symptoms of hypoxia.

Additional Indexing Words:
- Cyanoses
- Pulmonary congestion
- Cardiac decompensation
- Glenn procedure

Tricuspid atresia has been classified into two anatomic groups: type I, with normal position of the great arteries and type II, with transposed great arteries. Each type has been further subdivided by Keith and associates into three subgroups according to the degrees of pulmonary stenosis and the size of the ventricular septal defect. Type IC, defined as tricuspid atresia with a large ventricular septal defect and normal or large pulmonary artery, is the only category without transposition of the great vessels in which increased pulmonary blood flow occurs.

Although type IC accounts for about 12% of the reported cases of tricuspid atresia without associated transposition, it rarely has been reported as a cause of massive cardiac enlargement, pulmonary congestion, and mild, if any, apparent cyanosis. Over the past 5 years, four infants of a total of 18 known to have tricuspid atresia without transposition have presented in this manner. Of greater interest, however, is the change in these clinical manifestations over varying periods to those more characteristic of tricuspid atresia with a normal-sized heart, decreased pulmonary blood flow, and deep cyanosis in three of the four children. No previous report could be found of tricuspid atresia with such marked changes in clinical status.

Reports of Cases

Case A
J. W. was admitted to Children’s Hospital of Los Angeles for the first time on March 2, 1960 at 2 1/2 months of age because of increasing dyspnea and cough unaccompanied by fever. Previous to this he had been asymptomatic. A heart murmur had been noted at 1 month. Cyanosis had not been noted by family or physician.

The infant was in moderate respiratory distress with tachycardia. A systolic thrill with grade III, harsh pansystolic murmur along the left sternal border and hepatomegaly were noted. Cyanosis was not apparent. The hemoglobin was 14.5 gm%. The electrocardiogram showed left axis deviation and left ventricular hypertrophy (fig. 1). The roentgenogram showed a grossly enlarged heart and pulmonary vascular engorge-

Case B

T. C. was admitted at 3½ months of age on August 10, 1964 because of a 3-day history of vomiting and rapid, difficult breathing not accompanied by fever. Cyanosis had not been noted by family or physicians except for a questionable discoloration on crying. The mother had palpated a thrill over his precordium since he was 2 weeks of age.

The baby was in respiratory distress, but was not definitely cyanotic. A thrill and grade IV pansystolic murmur were noted. There was hepatomegaly. The hemoglobin was 14.8 gm% with a hematocrit of 44%. The electrocardiogram showed a mean frontal axis of $-30^\circ$ (fig. 1). Define left ventricular hypertrophy and mild p-pulmonary were present. The roentgenogram showed a grossly enlarged heart with pulmonary vascular engorgement (fig. 3).
A clinical diagnosis of tricuspid atresia probably with transposition of the great vessels and congestive cardiac failure was made and appropriate treatment was instituted. Cardiac catheterization with cineangiography was done on August 11, 1964 (table 1). The diagnosis of tricuspid atresia with a ventricular septal defect was confirmed. Transposition of the great vessels was not present (fig. 4).

At 14 months of age on July 6, 1965, the child was readmitted for repeat cardiac catheterization studies because of increasing cyanosis and dyspnea on exertion. Generalized cyanosis was obvious. There was no evidence of congestive...
failure and the thrill and systolic murmur were unchanged. His hemoglobin was now 18.7 gm% with a hematocrit of 56%. The chest roentgenogram showed a heart of normal size with diminished pulmonary vasculature (fig. 3). The repeat catheterization studies included an arterial oxygen saturation of 55% (table 1).

On July 6, 1965, a Glenn procedure was performed and the atrial septal defect was enlarged. One month following surgery left chylothorax was diagnosed. This was extensive enough to produce marked respiratory difficulty. The left thorax was drained and the chyle did not reaccumulate. The youngster has since been free of symptoms.

Case C

T. M. was admitted at 15 days of age on December 16, 1964 because of vomiting, poor feeding ability, and a heart murmur.

Slight cyanosis was noted only with crying. A systolic thrill and loud harsh pansystolic murmur

were present maximally at the fourth left intercostal space. No diastolic murmur was noted. There was minimal hepatomegaly. The child was irritable. The hemoglobin was 17.9 gm% with a hematocrit of 52%. The electrocardiogram (fig. 1) showed left axis deviation with left ventricular hypertrophy. The roentgenogram showed a grossly enlarged heart with bilateral pulmonary vascular engorgement.

On the basis of the experience of the preceding two cases, a clinical diagnosis of tricuspid atresia was made. On December 17, 1964, he underwent cardiac catheterization and cineangiographic studies (table 1). The diagnosis of tricuspid atresia without transposition of the great vessels was confirmed (fig. 5). The resting arterial oxygen saturation was 93%. The pulmonary artery was large as was the ventricular septal defect.

Because of increasing cyanosis and a marked decrease in the size of the heart and pulmonary vascular markings (fig. 6), repeat cardiac catheterization and cineangiography were undertaken on April 7, 1965 at 4 months of age (table 1).

An attempt was made to delay surgery but at 5½ months of age a severe hypoxic episode resulting in unconsciousness necessitated readmission. A Glenn procedure was performed. Two months following surgery, he was found to have a massive chylous pericardial effusion. Pericardial taps for relief of symptoms were necessary three times over a 2-month period before resolution occurred.

The child did well for the following year. However, because of an apparent increase in cyanosis with crying and marked decrease in the intensity of his systolic heart murmur, a third cardiac catheterization was done at 18 months of age (table 1). Dye-dilution curves showed no apparent left-to-right shunt at the ventricular level. Cineangiographic studies showed marked diminution in the size of the ventricular septal defect.

**Discussion**

The clinical course observed in these three youngsters was remarkably similar except for the timing of the hemodynamic changes (table 2). All under 4 months of age were admitted to the hospital in congestive cardiac failure. Cyanosis rather than being the predominant sign was recognized only in patient B. A similar clinical picture associated with tricuspid atresia without transposition of the great vessels could be found in only two previous reports.

Findings in our patients are in striking contrast to the statements of Keith and associates, Nadas, and Taussig that gross cardiomegaly or massive pulmonary vascular engorgement or both do not occur in tricuspid atresia without associated transposition of the great vessels.

The electrocardiograms (fig. 1) of these infants warrant little comment. All showed the left axis deviation and left ventricular hypertrophy characteristic of tricuspid atresia; p-pulmonale was not impressive.

All three of the infants had a systolic thrill and a loud harsh pansystolic murmur maximal at the lower left sternal border. In addition, the second sound was definitely but not

abnormally split in all. The pulmonic component was diminished. Though characteristic of the murmur created by a ventricular septal defect, the murmur in these cases was not unlike that produced by infundibular pulmonary stenosis.8

The initial cardiac catheterizations confirmed the excessive pulmonary flow because high systemic arterial oxygen saturations were obtained in all. In addition, angiocardiograms in the first and cineangiograms in the latter two confirmed the absence of transposition of the great vessels. A large ventricular septal defect and normal-sized main pulmonary artery were clearly seen in patients B and C in addition to a small right ventricular chamber (figs. 4 and 5).

Over a 4-year period patient A had fewer respiratory infections and became better nourished. This same change in clinical status occurred more rapidly in the other two infants—over a 10-month period in patient B, and over a 4-month period in patient C. Hypoxic spells occurred in all three. The electrocardiograms and the auscultatory findings remained constant. The changes in the chest roentgenograms, however, were as dramatic as the changes in symptomatology. The heart size significantly decreased as did the pulmonary vascular markings.

It is not possible to do more than speculate as to the exact nature of the anatomic changes which produced such a marked decrease in pulmonary blood flow. Several possibilities may be eliminated from consideration. A closing patent ductus arteriosus is unlikely both by the unchanging nature of the systolic murmur and by failure to opacify a ductus on the initial angiographic studies. Progressive peripheral pulmonary arteriolar obstruction must be considered as a possible cause of decreasing pulmonary flow. If such were the case, however, one would expect the loud, harsh pansystolic murmur to diminish in intensity and the pulmonary component of the second heart sound to become accentuated. Neither of these changes occurred. The murmur and second heart sound were unchanged. Additional evidence is the fact that a superior caval, right pulmonary arterial anastomosis significantly reduced symptoms in all three patients. If peripheral pulmonary vascular obstruction were present, adequate flow from the superior vena cava to the pulmonary artery could not be expected.

Two possible causes for the diminishing pulmonary blood flow deserve consideration: progressive infundibular pulmonary stenosis or a closing ventricular septal defect. Our studies do not conclusively establish which of these was the case. A closing ventricular septal defect seems the most likely explanation and supportive evidence may be found in the literature. Roberts and associates9 described the heart of a 27-year-old man dying of hypoxia with tricuspid atresia. Though the right ventricle was hypoplastic, the outflow tract, pulmonary valve, and pulmonary artery were only slightly smaller than normal. There was definite evidence of a ventricular septal defect which had closed. Brock10 has also described two hearts with tricuspid atresia and normal-sized pulmonary arteries with very small ventricular septal defects producing death from hypoxia. In addition, it may be remembered that, although approximately 12% of the patients with tricuspid atresia without transposition have normal-sized pulmonary arteries and pulmonary valves, only the cases reported by Astley and associates8 and Carey and Edwards4 could be found in which the patients died in heart failure with slight or no cyanosis, gross cardiomegaly, and pulmonary congestion. In both of these instances the ventricular septal defect was described as large.

The two studies on each of our patients at different periods of time confirmed that arterial oxygen saturation was decreasing. The arterial saturation dropped from 83 to 73% in patient A and the second study in his case was 1 year prior to onset of hypoxic spells and palliative surgery; from 75 to 55% in patient B; and from 93 to 55%, while crying, in patient C. Neither the right ventricle nor pulmonary artery were entered for measurement in any study. Comparative angiographic studies with injection of contrast medium into
the left ventricular chambers with the patients in the lateral position were equivocal (figs. 4 and 5). The pulmonary artery definitely remained large and no infundibular constriction could be outlined in the comparable studies.

Only patient C has had cardiac catheterization following surgery (table 1). This was indicated because his clinical status had changed; in addition to cyanosis, more marked with crying being noted, his systolic murmur had definitely diminished. No left-to-right shunt at the ventricular level was demonstrated with dye-dilution curves and only minimal amounts of contrast could be seen passing through the ventricular septal defect (fig. 5). In patient C, at least, it seems apparent that a closing ventricular septal defect is the cause of the progressive decrease in pulmonary blood flow.
