The Effects of Operation on the Echocardiographic
Features of Idiopathic Hypertrophic Subaortic
Stenosis

SUMMARY
Simultaneous cardiac catheterizations and echocardiograms were performed before and 6-12 months
following ventriculoseptomyectomy in 10 patients with idiopathic hypertrophic subaortic stenosis (IHSS) to
define the effects of operation on the echocardiographic features of IHSS. Preoperatively, the resting peak
systolic gradient ranged from 40-125 mm Hg and averaged 81 mm Hg. Postoperatively no gradient was
present in nine patients and one patient had a 15 mm Hg residual gradient. Echocardiographic obstruction
index averaged 54 msec/mm (range 35-85) preoperatively and was reduced to 12 msec/mm (0-67)
postoperatively. The markedly abnormal systolic anterior motion (SAM) of the anterior mitral leaflet present
in all preoperatively was diminished or absent following operation. The preoperative left ventricular outflow
tract dimension, calculated by echocardiogram at peak SAM, averaged 1.4 mm (range 0-5) and increased to
15 mm (3-25) following operation. Ventricular septal width averaged 18 mm (range 14-21) and posterior
wall thickness averaged 11 mm (range 7-13) and were unchanged following operation. Mitral valve diastolic
closing velocity, measured echocardiographically was not altered by operation (average 35 mm/sec before
and after operation), suggesting that significant changes in left ventricular compliance did not occur. The
echocardiogram in patients after ventriculoseptomyectomy demonstrates more normal mitral valve motion
and increased left ventricular outflow tract dimension. In some patients uneven mitral leaflet-septal contact
may produce significantly abnormal areas of SAM without obstruction.

RECOGNITION of idiopathic hypertrophic subaortic stenosis (IHSS) and the estimation of the
severity of the obstruction is possible by employing the noninvasive technique of echocardiography.1-3
This technique has also been useful in the assessment of interventions employed in the treatment of the
disease.4-6 The present study was designed to define the effects of operation on the echocardiographic features
of IHSS.

diograms were performed before and 6-12 months following
ventriculoseptomyectomy in 10 patients with IHSS. The
operative techniques employed are described elsewhere but
are a modification of the Morrow technique.5-6 The patients’
ages ranged from 9 to 68 years. The diagnosis of IHSS was
documented in each patient by retrograde and/or transseptal
left ventricular catheterization.7-9 During the course of
preoperative and postoperative catheterization, simulta-
neous echocardiograms and left ventricular inflow and
central aortic pressures were recorded during resting basal
conditions.
Echocardiographic studies were performed with the
patients supine and the transducer at the third or fourth in-
tercostal space near the left sternal edge. The transducer
was positioned using the sector scanning method so that
both anterior and posterior mitral valve leaflets were iden-
tified and maximal valve leaflet excursion was insured.10 The
right and left heart catheterizations were performed by the
percutaneous right femoral technique. Pressures were
measured using Statham P23Db transducers and Electronics
for Medicine Model DR-8 recorder. The echocardiograms
were obtained with a Smith Kline Ekoline-20A ul-
trasonoscope interfaced to a Honeywell 1856 strip chart
recorder using a 10 cm focused Aerotech transducer. The
echo signals were recorded continuously on light sensitive
paper and echocardiograms were processed for illustration
by a photomechanical transfer process.
The degree of outflow tract obstruction was quantitated echocardiographically using two techniques. The distance between the interventricular septum and anterior mitral leaflet at the point of maximal abnormal anterior systolic movement was determined preoperatively and postoperatively as a measure of the minimum left ventricular outflow tract dimension (fig. 1). The degree of obstruction was also assessed employing the obstruction index technique described by Henry et al. as the quotient of the duration of outflow tract narrowing and the mean interventricular septal-anterior mitral leaflet distance. Simultaneously the peak systolic subaortic pressure gradient was measured between the left ventricle and central aorta.

The anterior mitral valve diastolic closing velocity, or E to F slope, and ventricular septal and posterior wall thicknesses were determined before and following operation in each patient. The posterior left ventricular free wall and ventricular septal thickness were measured in ventricular diastole at the end of rapid ventricular diastolic filling (fig. 1).

Results

Preoperatively, left ventricular outflow obstruction was present in every patient (fig. 2); peak subvalvular gradient averaged 81 mm Hg and ranged from 40 to 125 mm Hg. Postoperatively, no gradient was observed in nine patients and one patient had a 15 mm Hg residual gradient. The preoperative echocardiographic findings in a typical patient with IHSS are illustrated in figure 3. The markedly abnormal systolic anterior motion of the mitral valve leaflets, the narrowed left ventricular outflow tract, the hypertrophied ventricular septum and the diminished diastolic descent rate of the anterior mitral leaflet are demonstrated simultaneously. A large left ventricular-aortic gradient is present. The findings in the same patient after operation are reproduced in figure 4. Marked diminution of systolic anterior motion of the anterior mitral valve leaflet and widening of the left ventricular outflow tract in systole are evident. The outflow tract dimension at the peak of abnormal mitral valve systolic motion averaged 1.4 mm (range 0-5) preoperatively. Postoperatively, the outflow tract

dimension increased to 14.9 mm (range 3-26 mm) (fig. 5); similar echocardiographic alterations were noted in five patients in whom echocardiograms were performed within 48 hours of operation.

Preoperatively, the echocardiographic obstruction index averaged 54 msec/mm (range 35-85 msec/mm). Postoperatively, the echocardiographic obstruction index average was reduced to 12 (range 0-67). In one patient, significant systolic anterior motion of the mitral valve leaflet persisted postoperatively with a residual obstruction index of 67 msec/mm; simultaneously measured left ventricular-aortic pressures revealed no gradient. This inconsistency may result from uneven septal apposition by the anterior mitral leaflet and has been described.11

The interventricular septal width averaged 18 mm (range 16-20) and posterior left ventricular free wall thickness averaged 11 mm (range 7-13) preoperatively. Postoperatively, septal width and posterior wall thickness were unchanged. Mitral valve diastolic closing velocity averaged 35 mm/sec (range 10-60) preoperatively and was unchanged following operation.

Discussion

The effectiveness of ventriculoseptomyectomy in the relief of obstruction and mitral regurgitation in IHSS has been well documented by postoperative catheterization studies.12 Echocardiographic assessment of systolic mitral valve motion following successful ventriculoseptomyectomy in most instances correlates well with the relief of the outflow tract obstruction. The simultaneous disappearance of the obstruction and reduction in abnormal systolic mitral valve motion substantiates the role of the mitral valve apparatus in the genesis of the obstruction. Occasionally abnormal systolic anterior motion with apparent obstruction persists in the absence of a measurable gradient. This may be due to uneven anterior leaflet-ventricular septal contact as described by King et al.11

A decreased diastolic closing velocity of the mitral valve (E to F slope) by echocardiogram has been commonly observed in subaortic stenosis and other forms of left ventricular outflow tract obstruction.13 This reduced diastolic closing velocity appears to represent

delayed atrial emptying and slow ventricular filling secondary to decreased left ventricular compliance. In the present study, the mitral valve diastolic closure rate was not significantly changed following operation suggesting that left ventricular compliance was not significantly altered 6 to 12 months following operation.

Detection of asymmetric septal hypertrophy by echocardiography appears to be valuable in the identification of patients with IHSS, particularly in those with latent obstruction. This study supports the observation of Henry et al. that the echocardiographically determined septal thickness in patients with IHSS is significantly greater than the posterior left ventricular free wall thickness. 

In the present study the echocardiographic measurement of septal and posterior wall thicknesses remained essentially unchanged postoperatively. Since the severity of the obstruction is independent of the relative degree of asymmetric hypertrophy, this finding is not unexpected.

When the postoperative echocardiograms were performed, there was no certainty that the area of septum scanned included the area of the ventriculoseptomyectomy. Since only 10 to 20 grams of tissue are removed, it is doubtful that this significantly alters the septal mass.

Ventriculoseptomyectomy relieves the abnormal systolic anterior motion of the mitral valve leaflets as well as left ventricular outflow tract obstruction. Since this occurs without echocardiographic evidence of early regression of septal or posterior left ventricular wall thickness or an alteration in ventricular compliance, the restoration of more normal mitral valve motion in systole appears to be the most important factor in establishing normal hemodynamics.

Conclusion

The abolition of obstruction and the simultaneously observed echocardiographic reduction of abnormal systolic mitral valve motion suggests that the mitral valve plays a very significant role in the genesis of the obstruction in IHSS. Ventriculoseptomyectomy abolishes outflow tract obstruction and ameliorates mitral regurgitation by restoring more normal mitral valve motion. Echocardiography provides a reliable and sensitive noninvasive means for serial evaluation of medical and surgical therapy in idiopathic hypertrophic subaortic stenosis.
