Reduction of Infarct Size by Oxygen Inhalation Following Acute Coronary Occlusion

By Peter R. Maroko, M.D., Paulo Radvany, M.D., Eugene Braunwald, M.D., and Sharon L. Hale, B.S.

SUMMARY

This study was carried out in order to determine the effects of the inspiration of O2-enriched air on the size of myocardial infarction. In 15 anesthetized dogs, epicardial electrograms were recorded from 10 to 14 sites on the anterior surface of the left ventricle before and after intermittent occlusion of the left anterior descending coronary artery or one of its major branches. In each dog, one occlusion was carried out while the fraction of inspired oxygen (FIO2) was 0.20 and the other while the FIO2 was 0.40. With an FIO2 of 0.20 the average ST-segment elevation (ST) was 4.0 ± 0.6 mV (SEM) and the number of sites exhibiting ST-segment elevations exceeding 2 mV (NST) 15 minutes following occlusion was 6.2 ± 0.7 sites; comparable values following occlusion with an FIO2 of 0.40 were 1.8 ± 0.4 mV (P < 0.01) and 2.7 ± 0.7 sites (P < 0.01), reflecting reduction in acute myocardial ischemic injury. An FIO2 of 1.0 did not decrease myocardial injury further. In 24 other dogs, occlusion was maintained for 24 hours. In nine dogs in which FIO2 was increased from 0.20 to 0.40 30 minutes after occlusion, myocardial creatine phosphokinase activity (CPK) was less depressed in sites having comparable levels of ST-segment elevation at 15 minutes than in dogs that resired an FIO2 of 0.20 during the entire 24 hours. All (54) sites with ST-segment elevations > 3 mV in the 0.20 FIO2 group showed early signs of myocardial infarction, while only 49% of such specimens showed infarction in the 0.40 FIO2 group. Thus, it is concluded that 0.40 FIO2 following an experimental coronary artery occlusion decreases acute ischemic injury and reduces the eventual development of necrosis, as evaluated by enzymatic and histological techniques.

The majority of in-hospital deaths subsequent to acute myocardial infarction result from cardiogenic shock or "pump failure" and a close correlation exists between this clinicophysiological syndrome and the findings of massive infarction of myocardial tissue at postmortem examination. Consequently, in an effort to reduce the high mortality associated with pump failure, efforts have been directed to reducing infarct size following coronary occlusion. Interventions that favorably alter the balance between myocardial oxygen supply and demand have also been found to reduce myocardial damage following coronary artery occlusion. Enrichment of oxygen in the inspired gas is easily achieved and widely used in the treatment of patients with acute myocardial infarction but its potential value in limiting infarct size is not clear. While innocuous in modestly increased concentrations, the prolonged and continuous inhalation of very high concentrations of O2 has been demonstrated to be hazardous. Accordingly, the goal of this investigation, carried out in anesthetized open chest dogs with experimentally induced coronary occlusions, was to ascertain whether and to what extent the doubling of inspired O2 concentration reduces ischemic injury, as well as whether or not the inhalation of 100% O2 provides any additional benefits.

METHODS

The effect of hyperoxia on myocardial damage following coronary artery occlusion was studied using two protocols. Protocol A: Thirty-six dogs, weighing between 18 and 25 kg, were anesthetized with sodium thiamylal (25 mg/kg) with respiratory maintained by a Harvard respirator. The heart was exposed through the fifth left intercostal space and was suspended in a pericardial cradle. The left anterior descending coronary artery (LAD), or its apical branch, was dissected free from the adjacent tissue and occluded intermittently when desired, using a Schwartz intracranial arterial clamp. As previously described, epicardial electrograms were obtained from ten to 14 sites on the anterior surface of the left ventricle, distributed in areas supplied by the occluded artery as well as in areas remote to it and presumably adequately perfused. Two occlusions of 20 min each were carried out with an interval of 60 min for reflow. In 15 dogs two successive occlusions using a fraction of inspired oxygen (FIO2) of 0.20 (20% O2 concentration) were carried out. In another 15 dogs the first occlusion was with an FIO2 of 0.20 and the second with an FIO2 of 0.40 (40% O2 concentration). In six additional dogs, the effects of an FIO2 of 0.40 during one occlusion were compared to those

HYPEROXIA AND INFARCT SIZE

during an occlusion in which the FIO₂ was 1.0 (100% O₂ concentration). Epicardial electrograms were recorded prior to each occlusion and at 5 min intervals during the 20 min occlusions. These changes in acute myocardial ischemic injury were analyzed using the average ST-segment elevation over the epicardium (ST) and the number of sites showing ST-segment elevation exceeding 2mV (NST). Changes in ST and NST show alterations in injury in the same animal, but the absolute values do not allow a comparison of the severity of injury between dogs. Any site which exhibited a QRS duration exceeding 0.065 sec on any single tracing (the average normal value equals 0.040 seconds) and therefore showing secondary lowering of ST-segment levels (QRS-STT gradient effect) was excluded from analysis for the entire experiment. The paired t-test was used to examine the differences between ST and NST in consecutive occlusions.

Protocol B: In 24 dogs the effects of inhalation of 0.20 FIO₂ and 0.40 FIO₂ mixtures on the size of myocardial infarctions, as defined histologically, and on myocardial necrosis, as reflected in myocardial creatine phosphokinase (CPK) activity, were compared. The surgical procedure was identical to the one used in Protocol A. However, in these dogs, coronary artery occlusion was maintained for 24 hours. Epicardial maps were recorded at 5 min intervals following coronary occlusion for 20 min, as described in Protocol A. The dogs' chests were then closed, they were extubated and allowed to awaken. Their arterial pressure was recorded by a Statham P23Db gauge through a polyethylene catheter inserted into the carotid artery and an electrocardiographic lead (aVR) was monitored constantly. Twenty-four hours following occlusion, the dogs were again anesthetized, their chests re-opened and the hearts excised immediately and washed in cold saline. Transmural specimens were obtained from the same sites at which epicardial electrograms had been recorded 24 hours earlier. The specimens were excised in the shape of rectangular blocks involving the thickness of the entire left ventricular wall. These specimens were analyzed for CPK activity, as previously described. The specimens were coded and prepared using Bouin’s fixation and hematoxylin and eosin stain. They were examined without previous knowledge of the origin of the biopsy for signs of early myocardial infarction, as reflected in a deeper eosinophilic appearance, karyorrhexis, karyolysis, polymorphonuclear infiltrate and membrane rupture, as described previously.

Fifteen of the 24 animals served as controls, i.e., they were maintained on room air for the 24 hour period. In the nine experimental animals, beginning 30 min following occlusion, i.e., 15 min following the epicardial mapping, the inhaled gas mixture was changed to one with an FIO₂ of 0.40. After extubation the dogs were placed in a chamber in which an FIO₂ of 0.40 was maintained until they were sacrificed 24 hr later. Although the investigator knew which dogs were controls and which were experimental, the myocardial specimens for histological appearance and CPK content were coded and were analyzed without previous knowledge of their site of origin or whether they were obtained from a control or experimental dog. The data were analyzed by relating ST-segment elevation at each site 15 min following occlusion to the transmural myocardial CPK activity and histological appearance 24 hr later.

Results

Protocol A: The effect of FIO₂ of 0.40 and 1.00 on acute myocardial ischemic injury.

In 15 dogs, the average ST-segment elevation (ST) and number of sites showing ST-segment elevations over 2 mV (NST) were similar following two consecutive occlusions with an FIO₂ of 0.20; STs after 15 min of each occlusion were 4.3 ± 0.7 and 4.0 ± 0.8 mV (NS) and the NSTs were 5.0 ± 2.0 and 5.0 ± 2.0 sites.

When the FIO₂ was raised from 0.20 to 0.40, the arterial pO₂ rose from 99 ± 5 to 185 ± 5 mm Hg. When the occlusion was carried out with an FIO₂ of 0.40, ST and NST were both lower than when the FIO₂ was 0.20 (fig. 1). In the 15 dogs so studied, ST 15 min following control occlusion was 4.0 ± 0.6 mV and was reduced to 1.8 ± 0.4 mV (P < 0.01) during the occlusion with an FIO₂ of 0.40 (fig. 2, left); NST decreased from 6.2 ± 0.7 to 2.7 ± 0.7 sites (P < 0.01) (fig. 2, right). It should be noted that although the interventions were not randomized, no difference was expected between the two occlusions as documented in the previous group of dogs.

In an additional group of dogs, when FIO₂ was increased from 0.40 to 1.00, the arterial pO₂ rose from 206 ± 14 to 550 ± 18 mm Hg. There were no significant differences in ST and NST 15 min following the two occlusions (fig. 3). In all six dogs so studied, STs were 4.9 ± 1.6 and 5.6 ± 2.0 mV (NS) and NSTs were 6.3 ± 1.4 and 6.3 ± 1.5 sites (NS), respectively, as FIO₂ was elevated from 0.40 to 1.00. At the same time heart rate and mean arterial pressure did not change significantly (from 140 ± 15 to 138 ± 15 beats/min and from 114 ± 10 to 122 ± 10 mm Hg). The ST and NST were purposely set at higher levels (by using dogs with larger infarcts) when comparing an FIO₂ of 0.40 with an FIO₂ of 1.00 than they were when comparing an FIO₂ of 0.20 with an FIO₂ of 0.40 in order to be able to detect decreases in injury with an FIO₂ of 1.00, if they did, in fact, occur.

Protocol B: The effect of FIO₂ 0.40 on infarct size.

In the control dogs, in which the FIO₂ was maintained at 0.20 throughout the 24 hr of coronary artery occlusion, CPK activity was depressed in sites with ST-segment elevations (figs. 4, 5 and table 1). There was an inverse relationship between ST-segment elevations at 15 min after occlusion and CPK activity 24 hr later: log CPK = -0.06 ST + 1.5 (r = 0.8). In these control dogs, all 54 sites with ST-segment elevations > 5 mV showed early signs of myocardial necrosis, as reflected by deepened eosinophilic appearance, karyorrhexis, karyolysis, polymorphonuclear cell infiltrate and disruption of the sarcolemma (fig. 4). In contrast, all sites with no or minimal ST-segment elevations 15 min following coronary artery occlusion revealed a normal histological appearance 24 hr later (fig. 4). Also, there was a good correlation between the histologic findings and...
Example of the effect of respiring 40% O\textsubscript{2} on the number of sites showing ST-segment elevation (NST) and on the average ST-segment elevation (ST). Right) Schematic representation of the heart. Lined area = area of ST-segment elevation 15 min following occlusion with FIO\textsubscript{2} of 0.20. Starred area = area of ST-segment elevation 15 min following occlusion with FIO\textsubscript{2} of 0.40. LAD = left anterior descending coronary artery. □ = sites from which epicardial electrograms were recorded. Left) Comparison between the average ST-segment elevation (ST) in the same animal after two occlusions. □ = ST just before and after occlusion with FIO\textsubscript{2} of 0.20. • = ST just before and after occlusion with FIO\textsubscript{2} of 0.40. Time = minutes after coronary artery occlusion.

In dogs in which the FIO\textsubscript{2} was raised to 0.40 30 min following occlusion (i.e., 15 min following the epicardial mapping) and in which this level of FIO\textsubscript{2} was maintained throughout the 24 hr of occlusion, many sites which exhibited ST-segment elevations 15 min after occlusion — and thus in control dogs would have shown signs of myocardial necrosis as reflected by CPK depression and histological appearance of early myocardial infarction — exhibited a normal histologic appearance (figs. 5 and 7, sites C and F). In all nine dogs exposed to an FIO\textsubscript{2} of 0.40, myocardial CPK activity was less depressed in sites having comparable levels of ST-segment elevation at 15 min than in dogs exposed to an FIO\textsubscript{2} of 0.20 (fig. 5 and table 1). The relationship between ST-segment elevation and CPK depression, in this group, was log CPK = -0.02 ST + 1.5 \ (r = 0.7).

significantly less steep than that of the control group ($P < 0.005$). In sites with moderate ST-segment elevation (4–5 mV), CK activity was significantly less depressed in the dogs in which FIO$_2$ was increased to 0.40 (fig. 5 and table 1) indicating that elevating the FIO$_2$ to 0.40 reduced myocardial necrosis, as reflected

### Figure 5

Relationship between ST-segment elevations 15 min following occlusion and CK activity in myocardial biopsies from the same sites 24 hr later in dogs breathing 20% oxygen (lined columns) and in dogs breathing 40% oxygen (dotted columns). Note that with no or minimal (0–3 mV) ST-segment elevations, CK activity was similar in the two groups but with moderate (4–5 mV) ST-segment elevations and with marked ST-segment elevations (≥ 6 mV) there was less CKP depression in dogs treated with 40% oxygen. Numbers in the columns represent the number of dogs. Each dog is weighted equally regardless of the number of sites sampled. Columns indicate the average of the mean values of CKP concentration at sites having stated ST-segment elevations for each dog. *$P = 0.08$ (two tails), **$P < 0.01$ (20% vs 40% $O_2$ inhalation). The CPK concentrations in the specimens with 4–5 mV and those ≥ 6 mV in either the control dogs or those treated with 40% $O_2$ did not differ significantly (4–5 mV vs ≥ 6 mV ST-segment elevation).

*Number of specimens in each dog with the above ST-segment elevations.
†CKP activity in international units/mg of protein. Mean value = 1 standard error when $N \geq 4$.

![Diagram](image)

**Figure 7**

in tissue CPK content; in sites with marked ST-segment elevation (≥ 6 mV) the directional changes were similar, but the difference in CPK concentration between the groups receiving 0.20 and 0.40 oxygen were of borderline significance (P = 0.08).

Sites that exhibited ST-segment elevations > 3 mV 15 min following occlusion, i.e., prior to commencing an FIO₂ of 0.40, exhibited signs of early myocardial infarction in only 49% (18/37) of specimens; thus histological signs of early myocardial necrosis were not present in half of the specimens in which it would have been expected had the FIO₂ remained at 0.20 (fig. 7). Just as was the case in the dogs that received an FIO₂ of 0.20 for 24 hrs, in the dogs that were exposed to an FIO₂ of 0.40, those sites that exhibited abnormal histologic findings of early myocardial necrosis had significantly lower CPK concentration than sites with normal histologic appearance (fig. 6).

There was no difference between mean arterial pressure, heart rate and the time of development of arrhythmias between the two groups of dogs (table 2). In this series of dogs, as well as in all of our previous experiments, the animals exhibited a lower arterial pressure 24 hr after occlusion than initially (table 2);
the mechanism of this reduction is not clear. In this model, ST-segment elevations decline with elevations of arterial pressure, and on the basis of earlier studies it is believed that arterial pressure is an important determinant of the extent of ischemic injury following coronary occlusion. Therefore, it is likely that if the arterial pressure had been held constant, infarcts both in the control and experimental groups would have been even smaller. Actually, arterial pressure declined even more in the group with an FIO2 of 0.40 as compared to that respiring 0.20 and the finding that the former group had smaller infarcts, despite greater reductions of pressure, strengthens the conclusion that an FIO2 of 0.40 reduced ischemic damage in dogs with coronary occlusion. Prior to occlusion and three and 24 hours after occlusion, the pO2 in the FIO2 0.20 and FIO2 0.40 groups were, respectively, 85 ± 2, 82 ± 3, and 79 ± 2 mm Hg and 85 ± 3.6 (NS), 191 ± 12 (P < 0.001), and 171 ± 4 (P < 0.001) mm Hg.

Discussion

Interventions which favorably affect the balance between myocardial oxygen supply and demand can significantly reduce the size of an infarction following coronary artery occlusion. Thus, beta-adrenergic blockade with propranolol and practolol as well as intra-aortic balloon counterpulsation and nitroglycerin by reducing myocardial oxygen requirements, reduce myocardial damage and/or necrosis following coronary occlusion; on the other hand, interventions which presumably increase coronary artery flow to the ischemic area, either through collaterals or by reperfusion of the occluded artery, reduce myocardial injury by increasing oxygen availability. In this investigation it was demonstrated that the inhalation of 40\% O2 reduced electrocardiographic evidence of acute myocardial ischemic injury as well as the extent of myocardial necrosis. Sites at the periphery of the damaged zone of myocardium, which showed lesser degrees of ST-segment elevation 15 min following coronary occlusion, were completely protected by an FIO2 of 0.40, while sites in the center of the damaged zone, with more severe ischemic injury, were partially protected. The histologic findings were consistent with this interpretation in that half of the sites which would have been expected, on the basis of studies in animals receiving FIO2 of 0.20, to exhibit early signs of myocardial necrosis were protected by an FIO2 of 0.40 and exhibited a normal histologic appearance. This finding, that enrichment of inspired O2 content reduced electrocardiographic evidence of ischemic injury, as noted in the epicardial ST segment following acute coronary occlusion, is reflected also in biochemical evidence of reduced myocardial injury (less CPK reduction).

The histologic and biochemical findings are internally consistent in that in dogs which were exposed to an FIO2 of 0.40: 1) as stated above, many sites which, on the basis of the ST-segment elevation, would have been expected to exhibit myocardial necrosis showed no histologic changes; 2) these same sites exhibited significantly less reduction of CPK concentration than if they had been exposed to an FIO2 of 0.20 (fig. 5); and 3) the concentration of CPK was significantly lower in the sites with histologic evidence of myocardial necrosis than in sites with normal histologic appearance (fig. 6), although the histologic assessment apparently is not sensitive enough to detect early necrosis in every site in which there was some reduction of CPK activity.

It is not known whether the reduction in myocardial CPK concentration represents CPK loss from the injured myocardium or decreased production. At least in part it represents loss into the plasma since a correlation exists between loss of myocardial CPK activity and the appearance of CPK in the plasma. Also, it has been shown that CPK leaks from the injured area through the lymphatics. The observed correspondence between depression of tissue CPK activity and histologic necrosis is consistent with earlier studies.

Our conclusions concerning the beneficial effects of an FIO2 of 0.40 are further strengthened by the observation that epicardial ST-segment elevation following coronary occlusion reflects reduction of cellular pO2 as well as alterations in the lactate, ATP and creatine phosphate concentrations of the subjacent heart muscle. A number of possibilities should be considered in the explanation of these findings. Oxygen administra-

Circulation, Volume 52, September 1975
tion increases total peripheral resistance which, in turn, may elevate arterial pressure and thus augment coronary artery perfusion pressure, decreasing myocardial damage. However, in these experiments, an \( FIO_2 \) of 0.40 did not produce a significant change in systemic arterial pressure, effectively excluding this explanation. Recently, Ishikawa et al. demonstrated that oxygen administration can reduce myocardial contractility in the ischemic zone following partial coronary artery occlusion and therefore, since myocardial contractility is a major determinant of myocardial \( O_2 \) consumption, it might be postulated that the reduction in infarct size with an \( FIO_2 \) of 0.40 is related to a decrease in myocardial oxygen needs. However, in two dogs the inhalation of 40% oxygen did not change left ventricular dp/dt or dp/dt/developed pressure, an index of myocardial contractility. While not excluding the possibility that regional contractility could be decreased by an \( FIO_2 \) of 0.40, this does not seem to be the most plausible mechanism, since a complete occlusion (in contrast to a partial occlusion) results in a noncontracting segment of myocardium, and thus contractility cannot decrease further.

With an elevation of \( FIO_2 \) from 0.20 to 0.40, arterial \( pO_2 \) increased from 99 to 185 mm Hg; this does not result in a substantial increase in the oxygen content of the blood and thus the marked reduction of ischemic injury cannot be explained simply on the basis of augmented oxygen delivery. This increase in arterial \( pO_2 \) also does not augment substantially the quantity of \( O_2 \) delivered to normal tissue, according to the considerations developed by Krogh and Kety. However, the possibility that an increased arterial \( pO_2 \) may enhance the diffusion of \( O_2 \) through an increase in the gradient between the normal and ischemic tissue cannot be excluded. Moreover, since the distribution of blood to the myocardium distal to an occlusion is often quite heterogeneous, the interface between normally perfused and ischemic tissue is much greater than the gross boundary of the infarct; thus, it is postulated that a deeper penetration of oxygen by only a small distance into the ischemic tissue might result in a substantial increase in the quantity of tissue that is sufficiently oxygenated to allow survival and that it might thereby decrease myocardial damage. If it is considered that the level of \( pO_2 \) required for function of the mitochondria is between 1 and 2 mm Hg, it becomes reasonable to consider that a minimal increase in \( pO_2 \) can favorably affect the energetic mechanism of myocardial cells, thus permitting their survival. Also, considering that oxygen may constrict the coronary arteries in normal tissue, there may be an increase in the pressure gradient between the normal and the ischemic area, diverting more blood to the injured zone. Therefore, it is postulated that increased availability of oxygen to the ischemic areas constitutes the mechanism by which an \( FIO_2 \) of 0.40 reduced damage following coronary occlusion. The finding that oxygen therapy is beneficial in decreasing infarct size is in accordance with the observation in patients with ischemic heart disease in which the threshold to pacing-induced angina and myocardial lactate metabolism have all been shown to improve with inhalation of oxygen enriched mixtures.

In this study the effect of an \( FIO_2 \) of 1.00 on the extent and severity of ischemic injury was not found to be more beneficial in reducing ischemic injury than an \( FIO_2 \) of 0.40. The reason for this is not clear, but since an \( FIO_2 \) of 0.40 as compared to 1.00 presents no danger of oxygen toxicity and since this modestly increased \( FIO_2 \) can be easily administered through a nasal catheter, it is suggested that an \( FIO_2 \) of 0.40 might be appropriate in the treatment of patients with acute myocardial infarction.

It is appreciated that extrapolation of these results to the clinical setting must of course be done cautiously, considering the many differences between man and dog, particularly as they relate to the richness of coronary collaterals and the fact that these studies were carried out on dogs with normal coronary vessels and myocardial function whereas most patients with myocardial infarction exhibit diffuse coronary obstructive lesions and myocardial damage. However, considering the substantial beneficial effects of an \( FIO_2 \) of 0.40 on the severity of ischemic injury and the size of infarcts following coronary occlusion, and its negligible adverse effects, the routine use of this treatment in patients with uncomplicated acute myocardial infarction would appear to be rational.

Acknowledgments

We gratefully acknowledge the technical help of Mr. Daniel White and Mr. Denis Hourihan and the secretarial assistance of Ms. Merilee Spence.
