Surgical Repair of Atrial Septal Defect in Patients over 60 Years of Age

Long-term Results

ANTOINE T. NASRALLAH, M.D., ROBERT J. HALL, M.D., EFRAIN GARCIA, M.D., ROBERT D. LEACHMAN, M.D., AND DENTON A. COOLEY, M.D.

SUMMARY In order to evaluate results of surgical repair of secundum atrial septal defect (ASD) in patients 60 years of age or older, a review was made of 16 patients who had undergone such operation between January 1964 and December 1974. Before operation eight patients were in functional classification III (New York Heart Association), seven were in class II, and one was in class I. Twelve patients had a left-to-right shunt greater than 3:1. Pulmonary artery systolic pressure was greater than 40 mm Hg in 12 patients and greater than 60 mm Hg in five. Four patients had documented paradoxical emboli and were being treated with Coumadin. Before operation all patients but one were receiving digoxin.

ATRIAL SEPTAL DEFECT (ASD) is the most common form of congenital heart disease encountered in adults. Of all congenital cardiac defects permitting survival beyond middle age, ASDs are the most common. The peculiar characteristic of ASD, setting it apart from other congenital heart defects, is the slow progress of the clinical course, which does not usually lead to debilitating symptoms until after the fourth or fifth decade. The success of surgery in treatment of middle-aged patients with ASD has been evaluated previously. Based on the favorable experience thus far gained, the opinion generally accepted is that surgical treatment is usually beneficial and is the treatment of choice, particularly in uncomplicated cases. Reports concerning older patients, however, are sparse and conclusions are contradictory.

General belief holds that elderly patients with ASD are not suitable candidates for surgical treatment. It appears appropriate then to report the detailed results of surgical correction of a number of these patients, aged 60 or over, who underwent operation at our institution.

Materials and Methods

From January 1964 through December 1974, 138 patients over the age of 45 years underwent surgical repair of a secundum ASD at the Texas Heart Institute. Of the 138 patients, 26 were over the age of 60. Among the 26 patients, ten had an associated lesion and all underwent concomitant surgical correction (table 1). This study is confined to evaluation of the 16 patients 60 years or older (range 60 to 76, with an average age of 65) who underwent surgical correction of isolated secundum ASD.

Repair was accomplished by direct suture in two patients and Dacron patch graft in 14. No deaths occurred during the postoperative period. Postoperatively, ten patients were in class I, five in class II, and one remained in class III. The hospital stay ranged from eight to 20 days (average 11 days). Two patients died one year and another (at the age of 77) five years after surgery. The remaining 13 patients are alive and well three months to 11 years after surgery.

We conclude that repair of secundum ASD in patients over the age of 60 is safe, has low morbidity, and produces considerable clinical improvement.

In these 16 patients, 13 women and three men, clinical assessment (history, physical examination, chest roentgenography and electrocardiography) was made and cardiac catheterization was performed before surgery. Repair of the defect in all patients was performed, under total cardiopulmonary bypass, by direct suture in two patients (12.5%) and Dacron patch graft in 14 patients (87.5%). Follow-up information on the 16 patients was obtained from their frequent visits to our institution, provided by written reply or telephone interview with the patient, or in most instances, from the referring physician.

Results

The clinical, hemodynamic and surgical results and follow-up data of 16 patients over the age of 60 who underwent surgical closure of secundum ASD are summarized in table 2.

Clinical Features

Eight patients were in functional class III, seven in class II, and one in class I. Four patients (25%) had paradoxical emboli with documented cerebrovascular accidents. Nine patients experienced palpitations. The chest roentgenogram revealed cardiomegaly in all but one of the 16 patients. Pulmonary vascularity was interpreted as normal in one and increased in 15 (93.5%). The chest roentgenogram suggested pulmonary hypertension (peripheral vascular "pruning") in two patients. Results of electrocardiography demonstrated normal sinus rhythm in eight patients (50%); atrial fibrillation and flutter or both in six (37.5%). Of the remaining two patients, one had paroxysmal atrial tachycardia and the other had a wandering pacemaker. Incomplete right bundle branch block consistent with right ventricular hypertrophy of the volume overload type was present in eight patients (50%) and complete right bundle branch block in seven (43%). Right axis deviation was observed in six patients (37%). All patients but one were being treated with digoxin in conjunction with other drugs preoperatively (table 2); four...
patients were receiving Coumadin for documented paradoxical emboli.

**Hemodynamic Data**

Pulmonary artery peak systolic pressure was less than 30 mm Hg in three patients (19%), 30-39 mm Hg in one (6%), 40-49 mm Hg in six (37.5%), 50-59 mm Hg in one (6%) and greater than 60 mm Hg in five (31%). Pulmonary vascular resistance, however, was moderately elevated in only two (12.5%) patients.

The magnitude of the left-to-right shunt through the ASD, expressed as a ratio of the pulmonary-to-systemic flow, is presented in table 2. A pulmonary-to-systemic ratio greater than 3:1 was found in 12 patients (75%).

The surgical mortality for all patients from age 45 on who had surgical repair of ASD is shown in table 3. In patients over the age of 60 with uncomplicated ASD no death occurred during the postoperative period. Hospitalization ranged from eight to 20 days (average 11 days). Minor postoperative complications occurred in nine patients. One patient who was known to have chronic lung disease developed bronchospasm and remained in the hospital for 20 days with no sequelae (table 2, patient 1). The sick sinus syndrome developed in one patient, postpericardiotomy syndrome in one, congestive heart failure in two, and rhythm disturbances including atrial fibrillation and/or flutter in four patients.

Two patients (12.5%) died one year after operation—one from myocardial infarction and another suddenly from unknown cause. One patient died five years after surgery, at the age of 77, from a cerebrovascular accident. Follow-up data from postoperative periods ranging from three months to 11 years (average 4.3 years) revealed the remaining 13 patients to be alive and well.

A comparison of the preoperative status and late postoperative functional classifications of the patients is shown in figure 1. Preoperative paradoxical systemic embolization in the single patient initially in class I and the three in class II indicated that surgery should be considered (table 2). After operation, 40% no longer required digitalis, 10% had no arrhythmia complications and 17% had no need for diuretic therapy (table 2).

**Discussion**

Controversy concerning the medical versus surgical management of elderly patients with ASD has remained un-
resolved largely because of the scarcity of information regarding the natural history of the disease in such patients. Although patients with ASD over the age of 60 may remain free of symptoms, disabling cardiorespiratory complications occur in most older patients. In our study all patients had significant symptoms before operation, and 50% experienced severe limitations (table 2). The presence of pulmonary hypertension, large left-to-right shunt, congestive heart failure, or atrial fibrillation has been reported to preclude surgical intervention because of a high operative mortality and, hence, many older patients with ASD were not considered candidates for operation. Previous reports indicated that operative mortality averaged approximately 6%, in patients over 45 years of age. Our over-all hospital mortality was 4.3% (6/138) in patients 45 and older, 7.9% (3/38) in patients with repair of associated defects, and 3% (3/100) in patients with repair of an isolated atrial defect alone (table 3). The hospital mortality was 10% (1/10) in patients over 60 years of age who had an associated procedure. There was no hospital mortality among the 16 patients 60 and over who had repair of uncomplicated ASD (table 3). The presence of pulmonary hypertension in the absence of a marked increase of pulmonary vascular resistance, a large left-to-right shunt, congestive heart failure and/or atrial fibrillation did not affect the outcome in this series, and the results of surgical treatment were favorable regardless of age. Because direct suture repair is more likely to distort the atrial septum and foster arrhythmias and recurrence, it has been our preference to utilize a knitted Dacron patch closure to prevent such complications.

The majority of survivors in this study uniformly experienced significant improvement and at present report no functional disabilities. These findings are consistent with those of Daicoff, et al., but are in contrast to those of Wolf, et al. Anticoagulant therapy was not used postoperatively and there has been no occurrence of systemic emboli in any of our patients, contrary to findings of another report.

Despite adequate medical treatment, most patients over the age of 60 with ASD have disabling and often progressive symptoms. The findings in our study indicate such patients have a large left-to-right shunt often accompanied by pulmonary hypertension. Paradoxical emboli occur more frequently than generally reported. In our experience surgical closure of ASD in patients above the age of 60 has proved to be successful and safe, with low morbidity even in patients with moderate pulmonary artery hypertension and moderately increased pulmonary vascular resistance, and large left-to-right shunt or congestive heart failure.
