Background. Increased platelet thromboxane (TXA₂) production has been described in type IIa hypercholesterolemia. To verify the relevance of these capacity-related measurements to the actual rate of TXA₂ biosynthesis in vivo, we studied the urinary excretion of its major enzymatic metabolites in 46 patients with type IIa hypercholesterolemia and 20 age-matched controls.

Methods and Results. Urinary 11-dehydro-TXB₂ and 2,3-dinor-TXB₂ were measured by previously validated radioimmunoassays. The excretion rate of 11-dehydro-TXB₂ was significantly (p<0.001) higher in patients (68.7±35.1 ng/hr, mean±SD) than in controls (22.4±9.4 ng/hr), with metabolite excretion >2 SD of the normal mean in 74% of the patients. Urinary 11-dehydro-TXB₂ was significantly (p<0.01) correlated with the threshold aggregating concentration of collagen (r=−0.641) and arachidonate (r=−0.734) and with agonist-induced platelet TXB₂ production in vitro (r=0.647 and 0.748, respectively). Moreover, a statistically significant correlation (r=0.673, p<0.001, n=66) was found between 11-dehydro-TXB₂ excretion and total plasma cholesterol. The enzyme 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitor simvastatin (20 mg/day for 6 months) significantly reduced cholesterol levels by 22–28% and urinary 11-dehydro-TXB₂ excretion by 32–42% in 10 patients. However, the reduction in the latter did not correlate with the reduction in the former and may have resulted from a nonspecific effect of simvastatin. Moreover, selective inhibition of platelet cyclooxygenase activity by low-dose aspirin (50 mg/day for 7 days) was associated with cumulative inhibition of 11-dehydro-TXB₂ excretion by approximately 70% in six patients.

Conclusions. TXA₂ biosynthesis is enhanced in the majority of patients with type IIa hypercholesterolemia; this is, at least in part, a consequence of abnormal cholesterol levels, as suggested by the correlation between the two. Low-dose aspirin can largely suppress increased metabolite excretion, thus suggesting that it reflects TXA₂-dependent platelet activation in vivo. (Circulation 1992;85:1792–1798)

Key Words • thromboxane • metabolites • simvastatin • aspirin

A high incidence of atherosclerosis and thrombotic complications has been associated with type IIa hypercholesterolemia.1 Because platelet hyper-reactivity has been considered responsible or at least contributing to acute thromboembolic complications such as myocardial infarction and ischemic stroke, several studies have assessed platelet function in type IIa hyperlipoproteinemia.2–8 Increased sensitivity of platelets to the aggregatory effects of various agonists and higher production of arachidonic acid metabolites have been described in hypercholesterolemia2–4 in association with increased activity of platelet phospholipases.3

Washed platelets from type IIa hypercholesterolemic subjects incubated with exogenous arachidonate produce higher amounts of thromboxane (TX)B₂, which correlates linearly with cholesterol levels.6 This abnormal platelet function has been related to the cholesterol content of platelets, possibly reflecting an exchange between plasma lipoproteins and platelets. In fact, platelets artificially enriched with cholesterol show enhanced sensitivity to aggregating agents and higher conversion of labeled arachidonate to TXB₂.7 Consistent with this hypothesis is the finding that the platelet content of cholesterol and phospholipids is significantly higher in patients with type IIa hypercholesterolemia than in controls and that this altered lipid composition is associated with enhanced production of TXA₂ by platelets.8

In the present study, we sought to determine whether the formation of this potent platelet agonist is altered in vivo through measurements of a major enzymatic metabolite of TXB₂ in the urine of patients with type IIa hypercholesterolemia and matched controls. Our results provide biochemical evidence for the occurrence of TXA₂-dependent platelet activation in vivo and for its relation to the plasma cholesterol level. Moreover, we demonstrate that enhanced TXA₂ biosynthesis can be

partially reduced by simvastatin, a selective inhibitor of the enzyme 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase, and largely suppressed by low doses of aspirin, a selective inhibitor of the enzyme prostaglandin (PG)G/H synthase.

**Methods**

**Subjects**

Forty-six patients with type IIa hypercholesterolemia (19 women and 27 men; age, 47±14 years; range, 20–66 years) and 20 healthy volunteers (10 women and 10 men; age, 42±13 years; range, 26–65 years) were studied on several occasions between March 1988 and May 1990. Informed consent was obtained from each participating subject. Type IIa hypercholesterolemia was defined in accordance with World Health Organization criteria,9 based on the determination of plasma total cholesterol and triglyceride levels as well as lipoprotein fractionation. Patients with diabetes mellitus, impaired hepatic function, secondary hypercholesterolemia, history of alcoholism (drug abuse), concomitant treatment with anticoagulants, antiplatelet drugs, corticosteroids, and theophylline were excluded. Moreover, we excluded patients with a history and/or clinical examination positive for evidence of macrovascular complications as judged on the basis of clinical symptoms, ECG monitoring during exercise, Holter monitoring, carotid Doppler testing, and Doppler echographic study of the lower limbs. Patients with renal disease (creatinine clearance <80 ml/min, serum creatinine >2 mg/dl, urine albumin excretion >300 mg/day) were also excluded. None of the patients had taken any drugs known to affect lipid metabolism or platelet function for at least 4 weeks before the start of the study. Patients were on a lipid-lowering diet (30% lipids, 52% carbohydrates, 18% proteins) with a polyunsaturated/saturated ratio of about 1.3 for at least 8 weeks before the study.

Nine patients were current smokers, and 37 never smoked or were ex-smokers who stopped smoking at least 2 years before the study. All healthy subjects were nonsmokers.

**Design of the Studies**

In the first study, a cross-sectional comparison of thromboxane metabolite excretion and platelet function was performed between the patients and controls. Both patients and controls were studied on an outpatient basis and fasted overnight before the study. Blood samples were obtained for measurement of platelet aggregation and TXB$_2$ synthesis in vitro. Urine was collected during the 12 hours before blood sampling; the samples were frozen immediately and kept at −20°C until extraction. Paired measurements of platelet synthesis of TXB$_2$ and aggregation in vitro and thromboxane metabolite excretion in vivo were obtained in 20 patients and 20 controls. The 20 patients (11 women and nine men) were nonsmokers.

To investigate prospectively the relation between blood cholesterol levels and thromboxane biosynthesis in vivo, we assessed the effects of a persistent reduction in cholesterol synthesis induced by an HMG-CoA reductase inhibitor in 10 of the above patients (seven men, three women; 26–55 years of age). Two of these patients were current smokers. The 10 patients were selected on the basis of a) indication to lipid-lowering drug therapy; b) no contraindication to simvastatin; c) willingness to participate in the study. The sample size was determined on the basis of the theoretical magnitude of thromboxane inhibition that could be reasonably expected from the correlation. Urine and blood samples were obtained before and after 1, 3, and 6 months of simvastatin (Merck Sharp & Dohme) treatment at a dose of 20 mg/day. The diet was controlled and remained unchanged throughout the study.

A third study was designed to examine the relative contribution of platelets to the enhanced excretion of 11-dehydro-TXB$_2$. For this purpose, six patients (four men, two women; 23–58 years of age; four current smokers) were given aspirin (Bayer) at a dose of 50 mg/day for 7 days, and 12-hour urine collections were obtained immediately before and on the third and seventh days of treatment. The six patients were selected on the basis of a) no contraindication to aspirin treatment and b) willingness to participate in the study. The sample size was determined on the basis of the expected reduction in thromboxane metabolite excretion, assuming a predominant platelet source of enhanced TXA$_2$ biosynthesis. In the same patients, the reproducibility of 11-dehydro-TXB$_2$ excretion was assessed by obtaining three additional urine samples during the week preceding aspirin administration. The studies were approved by the internal medicine review board of our institution.

**Lipid and Platelet Function Measurements**

Patients attended our lipid clinic in the morning after an overnight fast. All blood samples for lipid, lipoprotein, and apolipoprotein analyses were drawn into sodium and potassium EDTA (1 mg/ml). Cholesterol and triglycerides were determined enzymatically (Boehringer-Mannheim kit). High density lipoprotein (HDL) cholesterol was determined by the phosphotungstic acid (PTA)/MgCl$_2$ precipitation method (Boehringer-Mannheim). Low density lipoprotein (LDL) cholesterol was calculated by Friedewald’s formula (LDL = TC − HDL − HDL). Apolipoprotein B was quantified by Mancini’s radial immuno-diffusion method using plates with polyclonal antibodies (Daichi, Tokyo).

For platelet studies, blood was collected into 3.8% sodium citrate (1 ml for 9 ml of blood). Platelet-rich plasma and platelet-poor plasma were prepared as previously described. Platelet aggregation was measured in an ELVI 840 (Logos, Milan, Italy) aggregometer according to the method of Born after adjusting the number of platelets for each individual sample. For each agonist, the threshold aggregating concentration was defined as the lowest concentration of the agent that caused at least a 50% increase in light transmittance within 3 minutes. Platelet thromboxane synthesis was measured as previously described.

**Urinary 11-dehydro-TXB$_2$ and 2,3-dinor-TXB$_2$ Assays**

Measurement of urinary 11-dehydro-TXB$_2$ and 2,3-dinor-TXB$_2$ was performed by previously validated radioimmunoassay (RIA) techniques. Immunoreactive 11-dehydro-TXB$_2$ was extracted from 20-mI

Results

Thromboxane Biosynthesis and Platelet Function

Table 1 shows the mean lipid and apolipoprotein levels of patients and controls. Untreated type IIa hypercholesterolemic patients exhibited significantly (p<0.001) higher lipid levels than healthy subjects. Among hypercholesterolemic patients, there were statistically significant differences between smokers and nonsmokers in all lipid and lipoprotein measurements except for comparable triglyceride levels (Table 1).

Platelets from patients with type IIa hypercholesterolemia required significantly (p<0.01) less collagen and arachidonate to aggregate and synthesized greater amounts of TXB2 in response to both agonists than did platelets from healthy subjects (Table 2).

The urinary excretion rate of 11-dehydro-TXB2 averaged 22.4±9.4 ng/hr in the control group and 68.7±35.1 ng/hr in hypercholesterolemic patients (p<0.001). No statistically significant difference was found between men and women in either group. Among the patients, smokers had a significantly (p<0.01) higher excretion rate than nonsmokers (94.7±39.4, n=9 versus 62.4±30.8, n=37). In 34 (74%) of the 46 patients, metabolite excretion was more than 2 SD above the normal mean (Figure 1). To comparatively explore the metabolic disposition of endogenously released TXB2, aliquots of each urine collection (pH adjusted to 4.0–4.5 with formic acid), run on SEP-PAK C18 cartridges (Waters Associates, Milford, Mass.), and eluted with ethyl acetate. The eluate was subjected to silicic acid column chromatography and eluted with benzene:ethyl acetate:methanol (60:40:30). The overall recovery as assessed by 11-dehydro-[3H]-TXB2 averaged 80±6%. Immunoreactive 11-dehydro-TXB2 eluted from silicic acid columns was assayed at a final dilution of 1:15 to 1:1,000.

The authentic 11-dehydro-TXB2 used as the standard was a gift from Dr. J.E. Pike (The Upjohn Co., Kalamazoo, Mich.). Approximately 3,500 disintegrations per minute of 11-dehydro-[3H]-TXB2 was mixed with appropriately diluted antiserum (final dilution, 1:40,000) in a volume of 1.5 ml of assay buffer (Tris-phosphate-HCl buffer, 0.025 M, pH 9.2) and incubated for 16–24 hours at 4°C to obtain 40–50% binding of the tracer. Separation of antibody bound from free 11-dehydro-[3H]-TXB2 was achieved by rapidly adding 0.1 ml of blood bank plasma and 0.1 ml of a charcoal suspension (100 mg/ml) and subsequent centrifugation at 4°C. Unlabeled 11-dehydro-TXB2 displaced the binding of the homologous tracer in a linear fashion over the range of 1.0–50 pg/ml with an IC50 of 8.0 pg/ml. The cross-reactivities of 2,3-dinor-TXB2, TXB2, and 11,15-diketo-TXB2 were 0.1, 0.006, and <0.002%, respectively. As previously reported,13 comparison of urinary 11-dehydro-TXB2 excretion rates measured before, during, and after TXB2 infusion as determined by RIA and by capillary gas chromatography negative ion chemical ionization mass spectrometry yielded a highly significant linear correlation (r=0.958, n=15, p<0.0001). Stability of endogenous as well as exogenously added 11-dehydro-TXB2 in urine stored at −20°C was verified by assaying two separate sets of seven aliquots of the same urine sample without and with added standard, at time 0, 4 hours, 24 hours, and 7, 14, 21, and 28 days.15 Immunoreactive 11-dehydro-TXB2 averaged 7.59±0.55 and 73.07±5.62 ng (mean±SD, n=7), respectively, with no apparent decline as a function of storage.15

Immunoreactive 2,3-dinor-TXB2 was extracted from 20-ml urine samples run on SEP-PAK C18 cartridges and eluted with ethyl acetate. Eluted 2,3-dinor-TXB2 was separated from TXB2 on silica gel thin-layer chromatography (TLC) plates (60 F 254, E. Merck, Darmstadt, FRG). Details of the RIA procedure have been described elsewhere.14

Statistical Analysis

Data were analyzed by nonparametric methods to avoid assumptions on the distribution of the measured variables.16 An ANOVA was performed by the Kruskall-Wallis method. Subsequent pairwise comparisons were made by the Mann-Whitney U test. Associations of eicosanoid measurements with other biochemical and functional measurements were assessed by stepwise regression analysis and multiple linear regression. All values are reported as mean±1 SD. Statistical significance was defined as p<0.05.
through dehydrogenation of the hemiacetal alcohol group at C-11 vis-a-vis β-oxidation, we measured the urinary excretion of 2,3-dinor-TXB₂ in eight patients with type IIa hypercholesterolemia, encompassing excretory rates of 11-dehydro-TXB₂ between 8.8 and 83.5 ng/hr. A highly significant correlation was found between these paired measurements (r=0.929, p<0.001, n=8), with the ratio of 11-dehydro-TXB₂ to 2,3-dinor-TXB₂ averaging 1.4±0.4 (range, 0.6–2.1).

In both patients and controls, urinary 11-dehydro-TXB₂ was significantly (p<0.01) correlated with the threshold aggregating concentrations of collagen (r=-0.641) and arachidonate (r=-0.734) and with agonist-induced platelet TXB₂ production in vitro (r=0.647 and 0.748 for collagen and arachidonate, respectively). As shown in Figure 2, a statistically significant correlation (r=0.673, n=66, p<0.001) was found between 11-dehydro-TXB₂ excretion rates and total plasma cholesterol levels.

**Influence of Cholesterol Reduction**

Inhibition of cholesterol biosynthesis by the HMG-CoA reductase inhibitor simvastatin (20 mg/day for 6 months) was associated with statistically significant average reductions in both blood cholesterol levels by 22–28% and urinary 11-dehydro-TXB₂ excretion by 33–42% in 10 patients with type IIa hypercholesterolemia. Lipid changes are detailed in Table 3. The observed mean reduction in thromboxane metabolite excretion was consistent with the expected change that would be predicted by the correlation shown in Figure 2 if enhanced thromboxane biosynthesis were at least in part a consequence of elevated blood cholesterol levels. However, the response to cholesterol lowering by simvastatin was not homogeneous. Thus, in individual patients, thromboxane biosynthesis was reduced by as low as 10% to as high as 75% at any time point during simvastatin therapy, with no statistically significant correlation with the reduction in cholesterol levels (Table 4).

Effect of Low-Dose Aspirin

To characterize the enhanced excretion of 11-dehydro-TXB₂ in patients with type IIa hypercholesterolemia as being of platelet or nonplatelet origin, we evaluated the short-term effects of a platelet-selective regimen of aspirin therapy (50 mg/day for 7 days) on the degree of suppression of metabolite excretion in six patients. The lipid profile of these patients was: total plasma cholesterol, 304±21 mg/dl; plasma triglycerides, 125±25 mg/dl; HDL cholesterol, 48±7 mg/dl; LDL cholesterol, 231±23 mg/dl; apolipoprotein B, 176±8 mg/dl. Before aspirin administration, the rate of 11-dehydro-TXB₂ excretion averaged 78.5±43.8 ng/hr, with an intraindividual coefficient of variation of 10±3% as measured on four consecutive urine samples. After 3 days of aspirin administration, metabolite excretion was significantly (p<0.01) reduced to 40.0±21.4 ng/hr and at the end of 1 week was further reduced to 24.9±12.5 ng/hr (Figure 3). This finding is consistent with the cumulative nature of acetylation of platelet PGH/H synthase¹⁷ and inhibition of thromboxane biosynthesis¹⁸ by low-dose aspirin in healthy subjects.

Discussion

Several lines of evidence suggest that platelet hyperreactivity might be an important factor that contributes to the enhanced risk of thrombotic complications associated with a selective increase in plasma LDL cholesterol (reviewed in Reference 19). Thus, earlier studies in patients with type IIa hypercholesterolemia consistently demonstrated enhanced platelet aggregation in response to a variety of agonists and increased conversion of arachidonate through the platelet PGH/H synthase pathway to form proaggregatory eicosanoids such as PGH₂ and TXA₂.⁴⁻⁸

The results of the present study provide in vivo evidence of platelet activation in this type of patients in the absence of other cardiovascular risk factors known to influence TXA₂ biosynthesis.²⁰ The in vitro measurements of platelet aggregation and TXB₂ synthesis confirm and extend previous findings in patients with the same condition.¹⁹ However, both measurements represented capacity-related indexes and by no means reflect the actual occurrence of TXA₂-dependent platelet activation in vivo.²¹ Thus, the present study addressed the issue of the actual rate of TXA₂ biosynthesis in vivo through measurements of a major urinary metabolite, i.e., 11-dehydro-TXB₂.¹⁵ Approximately three quarters of our patients excreted two to seven times the level of metabolite measured in controls. In six patients in whom four different urine collections were obtained on consecutive days before aspirin administration, a relatively small intraindividual coefficient of variation (7–13%) was calculated, indicating a highly reproducible metabolic alteration. Because enhanced 11-dehydro-TXB₂ excretion might reflect either increased formation of TXA₂ or a shift in its metabolic disposition, we also performed paired measurements of 11-dehydro-TXB₂ and 2,3-dinor-TXB₂ in eight patients. The two metabolites reflect independent pathways of enzymatic degra-

![Figure 3](http://circ.ahajournals.org/)

**Figure 3.** Bar graph shows effects of low-dose aspirin (50 mg/day x 7 days) on urinary 11-dehydro-thromboxane (TX)B₂ excretion in six patients with type IIa hypercholesterolemia. Mean±SD values are represented for measurements performed before and during aspirin administration. Metabolite excretion was significantly (p<0.01) lower on the third and seventh days of aspirin administration compared with pretreatment measurements.
dation of TXB₂, i.e., 11-OH-dehydrogenation and β-oxidation, respectively. The fractional conversion of exogenously infused TXB₂ at 0.1–5.0 ng/kg min⁻¹ is comparable for the two metabolites and is independent of the rate of TXB₂ infusion in normal humans. Our finding of a close correlation between the excretory rates of 11-dehydro-TXB₂ and 2,3-dinor-TXB₂ is consistent with the hypothesis of unchanged metabolic disposition of endogenously released TXB₂ when its biosynthesis is pathologically increased in the setting of type IIa hypercholesterolemia. In the present series of patients, enhanced TXA₂ biosynthesis is unlikely to reflect known risk factors other than hypercholesterolemia inasmuch as a) they had a mean age of 47±14 years, thus excluding the influence of advanced age; b) they were not diabetics, thus excluding the possible contribution of altered metabolic control; c) they were selected for not having evidence of macrovascular complications; and d) 80% were nonsmokers.

The finding that smokers had higher TXA₂ biosynthesis than nonsmokers is consistent with previous observations in subjects without type IIa hypercholesterolemia. However, as detailed in Table 1, smokers also differed from nonsmokers in their lipid and lipoprotein levels. Thus, the relative contribution of smoking per se and the attendant lipid changes remains to be determined in the setting of type IIa hypercholesterolemia.

That enhanced TXA₂ biosynthesis in these patients may be, at least in part, a consequence of abnormal cholesterol levels is suggested by the correlation between the two (Figure 2). However, the reduction in thromboxane metabolite excretion associated with simvastatin treatment did not correlate with the reduction in blood cholesterol levels and may have resulted from a nonspecific effect of the drug. Simvastatin was previously shown to reduce platelet aggregation and TXB₂ synthesis ex vivo when given to patients with type IIa hypercholesterolemia for 6–8 months in a comparable dose range. The recent observation that the LDL receptor pathway has a regulatory role in eicosanoid formation through PGG₂/H⁺ synthase might be relevant to the present findings. However, because of the uncontrolled nature of the simvastatin study and heterogeneity of the observed changes in thromboxane metabolite excretion, this preliminary observation requires confirmation in a properly conducted placebo-controlled study.

Having established that there is indeed increased in vivo TXA₂ production in type IIa hypercholesterolemia, we tried to characterize its cellular origin. Because urinary enzymatic metabolites do not necessarily reflect a specific site of eicosanoid biosynthesis, we used a pharmacological approach to discriminate between platelet and nonplatelet sites of TXA₂ synthesis. We exploited the capacity of low-dose aspirin to selectively acetylate platelet PGG₂/H⁺ synthase in a cumulative fashion upon repeated daily dosing. In particular, renal cyclooxygenase activity, which can be a source of enhanced TXA₂ production under pathophysiological circumstances, is largely unaffected by daily doses of aspirin in the range of 20–50 mg. The finding of approximately 70% suppression in 11-dehydro-TXB₂ excretion after 1-week administration of low-dose aspirin as well as the cumulative pattern of metabolite reduction (Figure 3) are consistent with platelets representing a major source of enhanced TXA₂ production in type IIa hypercholesterolemia. In this context, it is interesting to note that the reduction in the risk of myocardial infarction associated with the long-term use of aspirin in a large population of healthy male physicians was apparent at all levels of cholesterol, including those ≥260 mg/100 ml. Although subgroup analysis suggests that the benefit was greatest at low levels of cholesterol, this may have reflected the small number of events in the <159 mg/100 ml group. Even in a trial as large as the Physicians Health Study, reliable identification of subgroups of subjects among whom treatment is particularly advantageous (or among whom it is ineffective) is unlikely to be possible.

**Summary**

Our studies demonstrate that TXA₂-dependent platelet activation does occur in vivo in the majority of patients with type IIa hypercholesterolemia without macrovascular complications. Whether inhibition of cholesterol biosynthesis may reduce the frequency or intensity of platelet activation remains to be firmly established. Moreover, low-dose aspirin may largely suppress enhanced TXA₂ formation in this type of patients. We would like to suggest that TXA₂-dependent platelet activation may represent a transduction mechanism linking this lipid disorder to the enhanced risk of vascular occlusive complications. This hypothesis can be tested by a controlled clinical trial of low-dose aspirin in hypercholesterolemic patients having major vascular events (i.e., myocardial infarction, stroke, and vascular death) as primary end points.
