Modulation by Dietary Salt of Verapamil Disposition in Humans

Dawood Darbar, MD; Martin F. Fromm, MD; Simonetta Dell’Orto, MD; Richard B. Kim, MD; Heyo K. Kroemer, PhD; Michel Eichelbaum, MD; Dan M. Roden, MD

Background—The intestine is an increasingly well-recognized site of first-pass drug metabolism. In this study, we determined the influence of dietary salt on the steady-state disposition of verapamil, a drug that undergoes extensive first-pass metabolism.

Methods and Results—Eight normal volunteers received 120 mg of racemic verapamil orally twice a day for 21 days. The disposition kinetics of verapamil enantiomers were determined after coadministration of intravenous deuterated verapamil with the morning oral dose on days 7, 14, and 21. Each study day was preceded by 7 days on a fixed-salt diet: in 5 subjects, the initial study was conducted during a low-salt (10 mEq/d) diet, the second study during a high-salt (400 mEq/d) diet, and the third during a low-salt diet, whereas in the other 3 subjects, the sequence of diets was reversed. Plasma concentrations of both unlabeled enantiomers (ie, from oral therapy) were significantly (P<0.05) lower during the high-salt phase (eg, mean area under the time-concentration curve [0 to 12 hours] for 6-verapamil: 7765±2591 ng·min·mL⁻¹ [high salt] versus 12 514±3527 ng·min·mL⁻¹ [low salt], P<0.05). Peak plasma concentrations were significantly lower and the extent of PR interval prolongation significantly blunted with the high-salt diet. In contrast, data with labeled drug (ie, reflecting the intravenous route) were nearly identical for the 2 diets.

Conclusions—These data indicate that a clinically important component of presystemic drug disposition occurs at the prehepatic (presumably intestinal) level and is sensitive to dietary salt. (Circulation. 1998;98:2702-2708.)

Key Words: diet ■ metabolism ■ sodium ■ stereoisomers

It is increasingly recognized that cytochrome P450 enzymes (CYPs) are expressed not only in the liver but also in the intestine and that the latter is an important site of drug metabolism.1,2 The major intestinal CYP in humans is CYP3A.3–5 CYP3A4 metabolizes both endogenous substrates6 and xenobiotics, including commonly used medications such as quinidine7 and verapamil.8,9 A number of studies have demonstrated that dietary interventions can alter expression of intestinal CYPs and their activity in both animals and humans.9–11 Recently, we have found that increasing dietary salt from 10 to 400 mEq/d reduced quinidine availability, determined after single doses of the drug, from 76±17% to 69±12%.12 Importantly, there was a much greater reduction in the area under the time-concentration curves (AUC) in the first hour after drug administration (from 1.6±0.6 to 0.6±0.4 µg·h·mL⁻¹), and there was no effect on elimination rate. Taken together, the data suggested that dietary salt modulated a prehepatic (most likely intestinal) component of quinidine disposition. However, the studies were conducted by administration of oral and intravenous doses of quinidine on separate days, an approach that may lead to experimental error because of day-to-day variability in drug disposition.

Verapamil undergoes greater presystemic extraction (>90%) than does quinidine, and multiple members of the CYP superfamily (CYP3A4, CYP1A2, CYP2C) contribute to its metabolism.8,13,14 It has been shown that during CYP3A induction by rifampin, prehepatic metabolism (presumably in the gut wall) plays a pivotal role in the first-pass metabolism of verapamil enantiomers.15 The finding of significant gut wall metabolism of verapamil, in turn, raises the possibility that this may also be a salt-sensitive component of verapamil metabolism. In clinical practice, verapamil is given in the racemic form, although its electrophysiological effects (eg, PR-interval prolongation) are attributable mainly to the S-enantiomer.16 In this study, we used a stable-isotope approach to evaluate the effect of dietary salt on the disposition of the S- and R-enantiomers of verapamil. Simultaneous administration of the unlabeled drug orally and deuterium-labeled drug intravenously was used to exclude day-to-day variability in drug disposition and to allow us to estimate the extent to which presystemic verapamil clearance is modulated by dietary salt during chronic oral drug administration.

Received June 17, 1998; revision received August 28, 1998; accepted September 9, 1998.

Methods

Human Subjects
Six men and 2 women (23 to 37 years old; mean, 29±7 years) participated. No clinically significant abnormalities were found by history, physical examination, or routine laboratory tests, including complete blood count, biochemistry, and ECG. No subject took long-term medications, and all refrained from caffeine and alcohol for the duration of the study. The protocol was approved by the Vanderbilt Institutional Review Board, and all subjects gave written informed consent before entry into the study.

Protocol
During the entire 21-day study period, each participant received 120 mg racemic, unlabeled verapamil twice per day (Isoptin, Knoll), and the disposition kinetics of verapamil were assessed on 3 occasions (Figure 1). The subjects were randomized to receive 1 of 2 dietary salt sequences. In 5 subjects, verapamil disposition was first assessed after 7 days of a low-salt (10 mEq/d) diet, then after 7 days of a high-salt (400 mEq/d) diet, and finally after 7 days of the low-salt diet (protocol A), with the order reversed in the other 3 subjects (protocol B). The 2 diets were prepared by the metabolic kitchen of the Vanderbilt Clinical Research Center to be identical, and supplementary salt tablets (20 mEq of sodium per tablet) were used to achieve the high-salt diet. The salt tablets were divided among the 3 meals.

The initial diet was continued for 7 days (to ensure both salt balance and steady-state concentrations of verapamil). On day 7 of the study, the disposition kinetics of verapamil were assessed by serial blood sampling over a 12-hour period, as described further below. After the 12-hour sample was obtained, the diet was switched to the next salt regimen and maintained for a further 7 days. Similarly, after the 12-hour sample on study day 14, the diet was switched back and maintained for a final 7 days.

On days 7, 14, and 21, subjects received 5 mg IV of deuterated racemic verapamil (d1,SR-verapamil; donated kindly by Knoll AG, Ludwigshafen, Germany) over 5 minutes, along with their usual morning dose of verapamil. On these days, no even dose of oral verapamil was administered. Blood samples (10 mL) were collected from the contralateral arm at times 0, 5, 10, 20, 30, and 45 minutes and 1, 1.5, 2, 3, 4, 6, 8, and 12 hours after the dose. An ECG was recorded with each blood sample. Urine was collected for the 12-hour period following the 20-minute, and the plasma was stored at 2°C versus t). 19

Statistical Analysis
An order effect was first sought, and none was found. Therefore, the pharmacokinetic analysis is presented in terms of the mean while on the 2 diets, ie, high-salt diet indicates that all the individual data from the high-salt phase of the 2 protocols were pooled together and the mean is presented. The same applies to the low-salt diet. Pharmacokinetic and pharmacodynamic parameters among the different parts of the study were compared by repeated-measures ANOVA with subsequent Student-Newman-Keuls pairwise tests if the null hypothesis of equal means could be rejected; P<0.05 was considered statistically significant. All data are presented as mean±SD.

Results
Five subjects were randomized to protocol A, ie, the dietary sequence low-high-low-salt diet, and the remaining 3 to the high-low-high sequence of diets (protocol B). Therefore, the total number of times subjects were on the high- and low-salt diets was 11 and 13, respectively. However, 2 subjects had 12-hour urinary sodium values >40 mEq while on low-salt
diets, and because of this noncompliance, their data from these study days were excluded from the final analysis. In fact, these 2 AUC0–12 values for unlabeled (oral) verapamil for both enantiomers were 2 SD lower than values for nonexcluded subjects, ie, the excluded data further support our major conclusion that the disposition of orally administered verapamil is sensitive to dietary salt. The remaining 12-hour urinary sodium excretions showed compliance with the diets (10.0 ± 8.8 mEq [low salt] versus 172 ± 65 mEq [high salt], P < 0.05). There was no significant difference in the weight of the subjects on the 2 diets (69 ± 15 kg [low salt] versus 70 ± 14 kg [high salt], P = NS).

Examples of plasma concentration-time curves (Figure 2) show that concentrations of unlabeled drug were lower with the high-salt diet, regardless of dietary order, whereas there was no effect on concentrations of the deuterated enantiomer. Significant differences (for both enantiomers) were observed in AUC0–t, particularly in the first 4 hours after a dose, and in Cmax (Table 1, Figure 3). The urinary recovery of each measured verapamil metabolite was higher (total, 34 ± 14%) with the high-salt diet (Table 2) versus 24 ± 10% on the low-salt diet (P = 0.09). The lower plasma concentrations during the high-salt diet were associated with a reduction in %ΔPR at 3 hours, from +14.9 ± 4.2% to +5.4 ± 2.8% (P < 0.01). In contrast to the data for unlabeled drug, data for deuterated S- and R-verapamil (Figure 4; Table 1) were virtually identical. In agreement with this finding, there was no significant difference in %ΔPR 5 minutes after intravenous verapamil on the 2 diets (+12.8 ± 3.4% [low salt] versus +12.6 ± 5.8% [high salt]).

Figure 5 shows the time course of unlabeled S- and R-verapamil trough levels from day 0 (start of a given diet) to day 7 (study day) on switching between diets. The data suggest that the transition between high- and low-salt diets was incomplete at 3 days and may have been incomplete even at 7 days. There was no significant difference in the mean liver blood flow on the 2 diets (1.54 ± 0.74 L/min [low salt] versus 1.57 ± 0.66 L/min [high salt]).

Discussion

Evaluation of systemic drug availability and the relative contributions of hepatic and extrahepatic drug metabolism requires reliable assessment of systemic and oral clearance. One study design uses separate oral and intravenous administration of drugs, assuming that no changes occur between study days. However, substantial intraindividual interday variations in drug metabolism have been observed.20 The simultaneous administration of labeled drug by one route and unlabeled by another provides a tool for the evaluation of systemic and oral clearance without the need to stop long-term oral dosing.20,21 In this study, the coadministration of deuterium-labeled verapamil by the intravenous route and unlabeled verapamil orally allowed the fate of the drug by both routes of administration, during long-term therapy, to be distinguished. This approach has the important advantage that it minimizes the problem of intraindividual variability in drug

Figure 2. Plasma concentration-time profiles for S-verapamil in a subject on protocol A (top) ie, sequence of low-high-low-salt diets, and protocol B (bottom), ie, sequence of high-low-high-salt diets. ■, S-Verapamil; ○, S-[2H]-verapamil.
clearance, which is particularly important when the bioavailability of high-clearance drugs such as verapamil is assessed. In addition, the use of deuterium-labeled drug avoids the use of a radiolabeled tracer. Using this approach, we have clearly shown that the increase in first-pass metabolism of both verapamil enantiomers with salt loading is unassociated with any change in disposition of intravenously administered drug. Thus, the difference between the fate of orally administered and intravenously administered drug must reflect a difference in drug disposition at a site to which the drug is preferentially exposed with administration by the oral compared with the intravenous route. The only such sites are the intestine and the portal circulation itself; thus, we infer a preferential effect of dietary salt on intestinal drug disposition. The ECG data were consistent with the plasma concentration data: %DPR after intravenous administration was comparable on the 2 diets, whereas %DPR after oral administration was significantly reduced on the high-salt diet. These results are similar to our earlier findings showing that dietary salt modulates the presystemic disposition of single doses of orally (but not intravenously) administered quinidine. In the present study, by using the stable-label approach, we were able to establish that this dietary salt effect is preserved during long-term oral therapy.

Potential Mechanisms
We considered that dietary salt might alter liver blood flow to contribute to changes in drug disposition, but we found no such change. A simple decrease in the extent of verapamil absorption with the high-salt diet seems unlikely, given the

trend toward increased urinary recovery of verapamil metabolites, whereas decreased recovery would be expected with decreased absorption. Indeed, this trend toward higher urinary metabolite concentrations with the high-salt diet supports the concept of increased metabolism at an extrahepatic site as an important underlying mechanism. As discussed above, the intestinal mucosa is increasingly recognized as a site of presystemic drug metabolism. For example, induction of CYP3A by rifampin increased the extent of cyclosporine metabolism to a greater extent than predicted from a hepatic effect alone, and a similar effect of rifampin on verapamil metabolism has been observed. Conversely, Gomez and colleagues reported that inhibition of cyclosporine metabolism by ketoconazole occurred to a similar or greater extent in the gut wall than in the liver, an effect attributed to inhibition of CYP3A. Most recently, Lown and colleagues have shown that ingestion of grapefruit juice inhibits metabolism of the calcium channel blocker felodipine, and with serial intestinal biopsies, they were able to demonstrate reduction of CYP3A expression in the intestinal mucosa. Intestinal drug metabolism by CYP3A may therefore be a major component of the salt sensitivity of drug disposition that we have demonstrated. The drug efflux pump P-glycoprotein is increasingly recognized to play a role in intestinal drug disposition, so variability in its expression or function is another possible contributor to the salt effect.

Dietary salt is known to modulate sympathetic function, and dietary salt on drug disposition may relate to an alteration in sympathetic activity, consistent with reported links between autonomic and gastrointestinal function. Another possibility is that increases in sodium or chloride concentration in the intestinal lumen serve as an initial signal for altered intestinal expression of genes encoding proteins such as CYP3A4 or P-glycoprotein.

**Clinical Implications**

These findings reinforce the notion that diet can be a major contributor to interindividual variability in drug disposition, eg, among ethnic groups. The findings may also be important in determination of drug bioavailability in conditions associated with altered salt balance. For example, it is known that, after the administration of equivalent doses, plasma quinidine concentrations are generally higher in patients with congestive heart failure than in control groups. The present findings support the idea that altered salt balance may contribute. Further, the common dietary recommendation to decrease salt intake in conditions such as hypertension or congestive heart failure may well modulate the response to the drug therapies used to treat the underlying disease.

**Limitations of the Study**

Although ICG clearance is widely used to estimate liver blood flow, the technique may involve significant assumptions, including that of instantaneous distribution into the
plasma compartment, changes in plasma protein concentration that may unpredictably alter intrinsic hepatic clearance of ICG, incomplete extraction, and the accuracy of the assay. However, ICG administration to estimate hepatic blood flow has been considered an especially useful approach in comparative studies.

A major advantage of the technique of coadministering labeled and unlabeled drug by different routes is minimization of day-to-day intrasubject variability in drug disposition. This approach thus allowed us to estimate the extent to which presystemic verapamil clearance is modulated by dietary salt by studying a relatively small number of subjects. This consideration has also been recognized to apply for drugs that do not undergo extensive first-pass metabolism.

In this study, each subject was studied on 3 separate occasions. The data therefore represent the analysis of 22 study days (11 each on low-salt diets and high-salt diets). If the data from only the 6 completely compliant subjects are reanalyzed (18 study days: 10 on low- and 8 on high-salt diets), the outcome is not changed.

Sex and genetic factors have been invoked to explain the widely recognized variability in CYP3A, although no strong data in support of this contention are available. Recently, we have found that intestinal and hepatic extraction of the probe drug midazolam are highly variable (regardless of sex) and have found that intestinal and hepatic extraction of the probe drug midazolam are highly variable (regardless of sex) and not correlated with each other. Indeed, the findings reported here raise the possibility that some of the recognized variability in CYP3A function may be attributable to variability in dietary salt.
