AHA Scientific Statement

Pet Ownership and Cardiovascular Risk
A Scientific Statement From the American Heart Association

Endorsed by the American Association of Cardiovascular and Pulmonary Rehabilitation, American Society of Hypertension, American Society for Preventive Cardiology, National Heart Foundation of Australia, Preventive Cardiovascular Nurses Association, and World Heart Federation

Glenn N. Levine, MD, FAHA, Chair; Karen Allen, PhD; Lynne T. Braun, PhD, CNP, FAHA; Hayley E. Christian, PhD; Erika Friedmann, PhD; Kathryn A. Taubert, PhD, FAHA; Sue Ann Thomas, RN, PhD; Deborah L. Wells, PhD; Richard A. Lange, MD, MBA, FAHA; on behalf of the American Heart Association Council on Clinical Cardiology and Council on Cardiovascular and Stroke Nursing

Cardiovascular disease (CVD) is the leading cause of death in the United States.1 Despite efforts promoting primary and secondary CVD prevention,2–8 obesity and physical inactivity remain at epidemic proportions, with >60% of Americans adults overweight or obese and >50% not performing recommended levels of physical activity.9 Similarly, hypertension, hypercholesterolemia, and other CVD risk factors remain poorly controlled in many Americans. Despite numerous pharmacological and device-based advances in the management of patients with established CVD, morbidity and mortality associated with this condition remain substantial. Hence, a critical need exists for novel strategies and interventions that can potentially reduce the risk of CVD and its attendant morbidity and mortality.

Numerous studies have explored the relationship between pet (primarily dog or cat) ownership and CVD, with many reporting beneficial effects, including increased physical activity, favorable lipid profiles, lower systemic blood pressure, improved autonomic tone, diminished sympathetic responses to stress, and improved survival after an acute coronary syndrome. Accordingly, the potential cardiovascular benefits of pet ownership have received considerable lay press and medical media coverage and attention from the Centers for Disease Control and Prevention10 and have been the focus of a meeting sponsored by the National Institutes of Health.11 The purpose of this American Heart Association Scientific Statement is to critically assess the data regarding the influence of pet ownership on the presence and reduction of CVD risk factors and CVD risk.

Pet Ownership and Systemic Hypertension
Some, but not all, studies of pet ownership and systemic blood pressure have found an association between pet ownership and lower blood pressure. An Australian study of 5741 participants attending a free screening clinic found that pet owners had significantly (P=0.03) lower systolic blood pressures than pet nonowners despite similar body mass index (BMI) and socioeconomic profiles.12 In a study of 240 married couples with or without pets, both systolic and diastolic blood pressures were significantly (P<0.01) lower in participants with a pet (dog or cat) than in those without a pet (Allen et al13 and personal communication from Karen Allen on P values, August 12, 2012). An online electronic survey of dog owners (n=536) and nonowners (n=380) found a greater adjusted odds ratio (OR) of self-reported hypertension in nonowners (OR, 1.71; 95% confidence interval [CI], 1.03–2.83).14 A study of 1179 subjects found that pet owners had lower systolic blood pressure (132.8 versus 139.5 mm Hg), pulse pressure (55.5 versus 63.9 mm Hg), and mean arterial pressure (105.0 versus 107.6 mm Hg) than nonowners and a lower incidence of hypertension (OR, 0.62; 95% CI, 0.49–0.80); however, after adjustment for age and other confounders, pet ownership was no longer associated with a lower blood pressure or incidence of hypertension.15 A community survey of 5079 middle-aged adults found pet...
owners and nonowners had similar systolic blood pressures, and those with pets had slightly higher diastolic blood pressures.16

The only randomized data on pet ownership and blood pressure come from a presented17 but unpublished study of 30 participants with borderline hypertension who were randomized either to adopt a dog from a shelter or to defer adoption of a dog. Ambulatory resting systolic blood pressure was similar in both groups at baseline (before dog adoption or deferred adoption). Ambulatory blood pressure monitoring 2 and 5 months after dog adoption demonstrated significantly (P<0.001) lower systolic blood pressures in the dog-adoption group than in the deferred-adoption group. Interestingly, at later follow-up, after all study participants had adopted dogs, systolic blood pressure was found to be similarly lowered in the deferred-adoption group as well.

Pet Ownership and Hyperlipidemia

There are minimal data on the association of pet ownership and lipid levels. In a study of 5741 participants attending a free screening clinic, male (but not female) dog owners had significantly but clinically modestly lower total cholesterol (201 versus 206 mg/dL; P=0.02) and triglyceride (108 versus 125 mg/dL; P=0.01) levels than nonowners of dogs.12 In a small (n=32) cross-sectional study of adults 260 years of age, pet owners had significantly lower triglyceride levels than pet nonowners (109 versus 192 mg/dL; P<0.01).18

In a cross-sectional online survey (n=916), dog nonowners were more likely to report elevated serum cholesterol levels and diabetes mellitus than dog owners who regularly walked their dogs.22 These findings persisted after controlling for owner’s age and intensity of physical activity but not after also controlling for BMI. In addition, tobacco use was more common among dog nonowners than dog owners.22

Pet Ownership and Physical Activity

Of all pets, dogs appear most likely to positively influence the level of human physical activity. Cross-sectional studies show that dog owners engage in more physical activity and walking and are more likely to achieve the recommended level of physical activity than nonowners.18–38 For example, data from an online survey of 5253 Japanese adults revealed that after controlling for age, sex, and socioeconomic status, dog owners engaged in significantly more walking and physical activity than nonowners and were 54% more likely to obtain the recommended level of physical activity.23 Similarly, an Australian study that controlled for sociodemographic, neighborhood, social environmental, and intrapersonal factors reported that dog owners engaged in significantly more minutes per week of physical activity (322.4 versus 267.1, P<0.001) and walking (150.3 versus 110.9, P<0.001) and were 57% more likely to meet the recommended level of physical activity than nonowners.24 A Canadian study (n=351) found that dog owners walked an average of 300 minutes per week compared with 168 minutes per week for nonowners (P<0.01), with the obligation to care for one’s dog being the key mediator of this association.25 After controlling for sociodemographic, health, and housing characteristics, the California Health Interview Survey found that dog owners walked 18.9 minutes more per week than pet nonowners.26 Some,23,32,33 but not all,39 studies of adolescents and children found a relationship between the presence of a family dog and physical activity. A meta-analysis of 11 studies found that dog owners walked significantly more and were more physically active than nonowners, with the differences between the 2 groups being small to moderate.40

Not surprisingly, dog owners who walk their dogs are more likely to achieve the recommended level of physical activity than dog owners who do not walk their dogs.25,26,41–44 Unfortunately, a significant proportion of dog owners do not regularly walk their dogs.25,27,31,36,43,45 No significant associations have been reported between physical activity and cat or other types of pet ownership.18,25,26,38,39,46

Several studies have assessed changes in physical activity after acquisition of a pet. A prospective cohort study of people who adopted either a dog or a cat from an animal shelter found a marked and sustained increase in the number and duration of recreational walks among those who adopted a dog but no or little change among those who adopted a cat or no pet (Figure 1).46 Similarly, a longitudinal study of Western Australians taking part in the Residential Environments (RESIDE) project found that self-reported recreational walking increased 22 to 31 minutes per week among those who acquired a dog.47 The primary mechanism through which acquisition of a dog leads to an increase in physical activity is believed to be behavioral intention (via the dog’s positive effect on the owner’s cognitive beliefs about walking), as well as motivation and social support for walking.48

Pet Ownership and Obesity

Participation in physical activity jointly by pets and humans is one mechanism whereby pet ownership may reduce obesity. The other important role that pets play in human health is social support, which is one of the most powerful predictors of adoption and maintenance of behavior change,49 including weight loss.50,51 Companion animals may strengthen engagement in a weight loss program by providing encouragement and motivation and reducing perceived barriers (ie, concerns about neighborhood safety) that hinder exercise.52,53 Accordingly, numerous studies have examined whether pet ownership is associated with a lower incidence of obesity and whether pet ownership enhances weight loss programs among obese people.

Observational studies that have examined how weight status varies among households with and without pets have yielded conflicting results, in part because of differing patient populations, types of pet studied, and human-pet interactions (ie, animal walking versus ownership). “Low-quality” observational studies (ie, nonrandom subject sampling, no adjustment for confounding factors) comparing pet owners and nonowners have found similar21,15 or higher24 BMI for pet owners. Similarly, an analysis of National Health and Nutrition Examination Study (NHANES) III data showed no difference in the incidence of being overweight (BMI ≥25 kg/m²) between pet nonowners (56%), dog owners (53%), and other pet owners (58%; P=0.09).34

In contrast, dog walking, as opposed to pet or dog ownership, does appear to be associated with a lower incidence...
of obesity. An observational epidemiological study of 2199 subjects noted significantly fewer obese (BMI $>30$ kg/m$^2$) dog walkers (17%) compared with both owners who did not walk their dogs (28%) and nonowners (22%). In this study, dog walking was associated with a higher proportion of participants who met national recommendations for moderate to vigorous physical activity (53%) compared with those who had owned but did not walk their dog (33%) and dog nonowners (46%). Similar results were noted in a recent study showing that individuals who did not own a dog had nearly a 2-fold greater odds (OR, 1.92; 95% CI, 1.45–2.56) of being overweight (BMI $>25$ kg/m$^2$), whereas those who did not walk their dog had a 60% higher odds (OR, 1.58; 95% CI, 1.07–2.33) of being overweight compared with dog walkers. In one study of younger children, the odds of being overweight or obese were lower among those whose family owned a dog than among families without a dog (OR, 0.5; 95% CI, 0.3–0.8).

Whether people walking with their dogs would lose more weight after 1 year than people walking alone was assessed in the People and Pets Exercising Together (PPET) Study. Thirty-six pairs of overweight or obese people with an obese pet and 56 overweight or obese people without pets participated in a 1-year prospective, controlled weight loss study in which people received dietary and physical activity counseling and dogs were fed a calorie-controlled prescription diet. Both people and their pets successfully lost weight; however, obese pet owners had similar weight loss as those without pets (4.7% versus 5.2%, respectively; $P$=NS).

**Pet Ownership and Autonomic Function and Cardiovascular Reactivity**

A positive or beneficial relationship between pet ownership and autonomic function or cardiovascular reactivity to stress has been reported in most but not all published studies. For example, cardiovascular reactivity to stress (ie, mental arithmetic and cold pressor) was assessed in 240 couples, half of whom owned a cat or dog. People with pets had significantly lower resting baseline heart rates and blood pressure, significantly smaller increases in heart rate and blood pressure in response to stress, and faster recovery of these parameters to baseline after cessation of stress. Reactivity to stress was lowest and recovery fastest in couples tested when their pet was present.

One published randomized study on pet ownership and cardiovascular reactivity was identified. As part of a study of blood pressure response to mental stress, 48 hypertensive patients with a high-stress occupation who were interested in stress reduction and had agreed to acquire a pet if chosen to do so were randomized to acquire or not acquire a pet. Physiological responses to mental stress were assessed before pet adoption and 6 months later, with pets present for those who had adopted them. Compared with pet nonowners, those who adopted a pet had similar physiological responses to mental stress at baseline but significantly diminished increases in systolic and diastolic blood pressure, heart rate, and plasma renin activity when exposed to mental stress at 6 months (Figure 2).

Two studies measured heart rate variability with 24-hour Holter monitors to assess autonomic function. In people with $\geq 1$ cardiac risk factor, pet (primarily dog or cat) owners (n=82) had greater elevated parasympathetic and diminished sympathetic nervous activities than nonowners (n=109), which indicates that pet ownership (1) attenuated the imbalance in autonomic nervous activity among patients with lifestyle-related diseases and (2) was associated with greater adaptability to perturbations in the cardiovascular system. Among 102 post–myocardial infarction patients, owners of pets (dogs or cats) had significantly higher heart rate variability than nonowners, which has been associated with decreased cardiac mortality among such patients.

Although most studies of autonomic and cardiovascular reactivity involved dogs or cats, several studies demonstrated beneficial effects on these parameters associated with goat, fish, chimpanzee, and snake ownership. One experiment even demonstrated a benefit on cardiovascular stress responses with “virtual” animals, which were presented in the form of video recordings.

**Pet Ownership and Survival in People Without Established CVD**

There are scant data on pet ownership and survival in people without established CVD. Analysis of data from a
large national health survey (published in an open-access journal) did not find a survival advantage associated with pet ownership. Likewise, analysis of data from the NHANES II, a longitudinal cohort study, did not find pet ownership was associated with reduced overall mortality.

Pet Ownership and Survival in Patients With Established CVD

Pet ownership is an important nonhuman form of social support and may provide cardioprotective benefits in patients with established CVD. In a substudy of the Cardiac Arrhythmia Suppression Trial (CAST), 1-year survival data were assessed in 369 study participants on the basis of whether or not the participant owned a pet. Overall, pet ownership of any kind tended to be independently associated with survival ($P=0.085$). Dog ownership was strongly associated with decreased mortality, with the likelihood of mortality being 4.05 times greater for dog nonowners than for dog owners ($P<0.05$); the benefit of dog ownership on survival was independent of physiological measures or the severity of CVD. Cat ownership was not found to be associated with decreased mortality or cardiac-related rehospitalization.

One-year survival was prospectively assessed in 96 patients admitted to a cardiac care unit or intensive care unit with myocardial infarction or angina pectoris. At 1-year follow-up, 11 (28%) of 39 pet nonowners had died compared with only 3 (6%) of 53 pet (primarily dog) owners ($P=0.05$); the benefit of dog ownership on survival appeared to be independent of age and the physiological severity of CVD. A post hoc analysis of survivors of myocardial infarction who were followed up in the Psychosocial Responses in the Home Automated External Defibrillator Trial (PR-HAT) found that lack of pet ownership was a significant ($P=0.036$) predictor of mortality.

In contrast to the findings in the above studies, a study of 412 patients with acute coronary syndrome found that the 1-year risk of readmission or cardiac death was not statistically different between dog owners and nonowners (OR, 1.59; 95% CI, 0.759–3.321; $P=0.22$) and was greater in cat owners than in nonowners (OR, 3.22; 95% CI, 1.44–7.19; $P=0.004$).

Summary, Conclusions, and Recommendations

A summary of the most relevant studies of pet ownership and cardiovascular risk is given in Table 1. Table 2 displays the American College of Cardiology Foundation and American Heart Association scheme for the classification of recommendations and level of evidence. The writing group’s conclusions and recommendations using this classification scheme are listed below.

Conclusions

- Pet ownership, particularly dog ownership, is probably associated with decreased CVD risk (Level of Evidence: B).
- Pet ownership, particularly dog ownership, may have some causal role in reducing CVD risk (Level of Evidence: B).

Recommendations

1. Pet ownership, particularly dog ownership, may be reasonable for reduction in CVD risk (Class IIb; Level of Evidence B).
2. Pet adoption, rescue, or purchase should not be done for the primary purpose of reducing CVD risk (Class III; Level of Evidence C).

Methodological issues in many studies of pet ownership and CVD include modest numbers of subjects, confounding factors (eg, sociodemographics, comorbid medical conditions,

• After adjustment, dog walking was independently associated with meeting PA guidelines (OR, 1.59; \(P=0.004\)) |
| Anderson et al\(^{12}\)   | Observational study of dog owners (n=784) and non–dog owners (n=4,957) attending a free screening clinic | • No difference in BMI between dog owners and nonowners |
| Coleman et al; NQLS\(^{44}\) | Observational study of dog owners and nonowners enrolled in NQLS (n=21,999)                     | • Significantly fewer obese (BMI >30 kg/m\(^2\)) dog walkers (17%) than either owners who did not walk their dogs (28%) or nonowners (22%)  
• No difference in overweight (BMI >25 kg/m\(^2\)) status among dog walkers, (60%) dog owners who did not walk their dogs (62%), and nonowners (56%) |
| Gillum et al; NHANES III\(^{34}\) | National health survey (n=11,394) of pet owners and nonowners (NHANES III)                      | • No difference in incidence of being overweight (BMI >25 kg/m\(^2\)) between non–pet owners (56%), dog owners (53%), and other pet owners (58%; \(P=0.09\)) |
| Kushner et al; PPET\(^{44}\) | Prospective, controlled study (n=92) of weight loss in dog owners and nonowners                  | • Obese patients with dogs and those without dogs enrolled in comparable weight loss programs had similar weight loss at 12 months (4.7% vs 5.2%, respectively; \(P=\text{NS}\)) |
| Timperio et al\(^{25}\)   | Observational study of dog owners and nonowners including children (n=1,145) and their parents (n=1,108) | • The odds of being overweight or obese were lower among younger children who owned a dog (OR, 0.5; 95% CI, 0.3–0.8) and higher among mothers whose families walked the dog together (OR, 1.3; 95% CI, 1.0–1.7)  
• Compared with dog walkers, those who did not own or walk their dog reported less PA (MET-min per week) and a higher BMI (\(P<0.01\)) |
| Lentino et al\(^{14}\)    | Observational online study (n=916) of dog owners and nonowners                                   | • Birds were associated with maternal overweight or obesity (OR, 1.55; 95% CI, 1.25–1.93; \(P=0.001\)) after adjustment for confounding factors  
• Cat ownership was associated with maternal overweight or obesity (OR, 1.27; 95% CI, 1.00–1.62; \(P=0.05\)) after adjustment for confounding factors |
| Parslow et al\(^{14}\)    | Observational study of randomly selected Australian electorate (n=5,079) of pet owners (dogs, cats, birds, or fish) and nonowners | • Pet owners had higher BMI than nonowners (26.85 vs 26.36 kg/m\(^2\), respectively; \(P<0.002\)) |
| Wright et al\(^{15}\)     | Observational community survey (n=1,179) of pet owners (dogs, cats, birds, hamsters, gerbils, others) and nonowners | • Pet owners were more likely to be overweight (defined as BMI >25.0 kg/m\(^2\)) than those who did not own pets (58% vs 46%), although mean BMI was similar between groups (mean=25.4 and 25.7 kg/m\(^2\), respectively) |
| Westgarth et al\(^{19}\)  | Observational study of pregnant women with or without pets (n=14,273)                            | • No association between dog ownership and weight status  
• Bird ownership was associated with maternal overweight or obesity (OR, 1.55; 95% CI, 1.25–1.93; \(P=0.001\)) after adjustment for confounding factors  
• Cat ownership was associated with maternal overweight or obesity (OR, 1.27; 95% CI, 1.00–1.62; \(P=0.05\)) after adjustment for confounding factors |

Cardiovascular reactivity and autonomic function

Allen et al\(^{39}\) Randomized, controlled 6-mo clinical trial of 48 stockbrokers with BP >160/100 mm Hg treated with ACE inhibitor and randomized to pet (dog or cat) adoption or no adoption  
• ACE inhibitor therapy alone lowered resting BP, but not BP reactivity to mental stress (\(P<0.001\))  
• Combination of ACE inhibitor therapy and pet ownership lowered BP responses to mental stress (\(P<0.001\))  
• Cats and dogs were associated equally with lower BP responses to mental stress  
• Relative to people without pets, people with pets had:  
  – lower resting BP and heart rate (\(P<0.001\))  
  – smaller increases in heart rate and BP from baseline level during mental and physical stress (\(P<0.001\))  
  – faster recovery (back toward baseline) of heart rate and BP from mental and physical stress (\(P<0.001\))  
• Cats and dogs were associated equally with lower responses to and recovery from stress  
• Pets elicited the lowest reactivity to stress, whereas spouses caused highest

(Continued)
and unidentified differences between those who choose to own or not own pets), differing pet populations, post hoc (ie, not prospective) analyses, and (understandably) lack of randomized data. Nevertheless, there are a number of methodologically sound studies, and there is a substantial body of data that suggests that pet ownership is associated with a reduction in CVD risk factors and increased survival in individuals with established CVD. The data are most robust for a relationship between dog ownership and CVD risk reduction, particularly dog ownership and increased physical activity. Whether this is attributable to dogs being the pets most commonly owned and studied, dogs being the pet most likely

<td>Friedmann et al79</td>
<td>Cohort analysis of patients hospitalized for coronary artery disease (n=92) who either owned or did not own a pet</td>
<td>Pet owners were more likely to survive for 1 year than nonowners (94.3% vs 71.8%, respectively; P&lt;0.002); Owners of pets other than dogs were more likely to survive for 1 year than pet nonowners (100% vs 71.8%, respectively; P&lt;0.05); Pet ownership added significantly to the prediction of 1-year survival beyond the contribution of physiological severity of disease (P&lt;0.004)</td>
</tr>
<tr>
<td>Friedmann et al79</td>
<td>Cohort analysis of pet (dog or cat) ownership and all-cause 1-year mortality in patients with ventricular arrhythmias after MI (n=369)</td>
<td>In univariate analysis, dog ownership predicted survival (P&lt;0.05). Neither pet ownership (dog or cat) nor cat ownership predicted survival. After adjustment for numerous factors, not owning a dog made a significant independent contribution to mortality (OR, 0.11; P&lt;0.05); not owning a cat did not make a contribution to mortality.</td>
</tr>
<tr>
<td>Friedmann et al80</td>
<td>Cohort analysis of pet ownership, depression, and all-cause mortality with a median follow-up of 2.8 years among patients who had an MI ≥6 months previously (n=460)</td>
<td>Not owning a pet predicted mortality in multivariate Cox regression (HR=0.972; P=0.045); after controlling for depression score (HR=1.228, P=0.782) and the interaction between pet ownership and depression. There was a tendency for an interaction between pet ownership and depressive symptoms for predicting time to death; depressed patients who did not own pets were 75% more likely to die than depressed patients without pets (HR=1.757; P=0.092)</td>
</tr>
<tr>
<td>Parker et al81</td>
<td>Cohort analysis of pet (dog or cat) ownership and combined outcome of cardiac rehospitalization or cardiac mortality within 1 year among patients hospitalized for coronary artery disease (n=412)</td>
<td>People with a pet in their household were more likely to experience a cardiac readmission or cardiac death than people who did not have a pet in their household (22.3% vs 14.5%; P=0.061); People who owned a dog tended to be more likely to experience a cardiac rehospitalization or cardiac death than people who did not own a dog (27.3% vs 16.2%, respectively; P=0.071)</td>
</tr>

</table>

ACE indicates angiotensin-converting enzyme; BMI indicates body mass index; BP, blood pressure; CAST, Cardiac Arrhythmia Suppression Trial; CI, confidence interval; CVD, cardiovascular disease; DBP, diastolic blood pressure; HR, hazard ratio; MET-min, metabolic equivalent minutes; MI, myocardial infarction; NHANES, National Health and Nutrition Examination Survey; NQLS, Neighborhood Quality of Life Study; OR, odds ratio; PA, physical activity; PPET, People and Pets Exercising Together; and SBP, systolic blood pressure.
to increase their owner’s physical activity, or additional other beneficial effects of dog ownership is uncertain. Given that most studies are nonrandomized, it cannot be determined with confidence whether the reduction of CVD risk factors with pet ownership is merely associative or causative, although there are plausible psychological, sociological, and physiological mechanisms for causation for many of the associations, particularly dog ownership and increased physical activity.

The writing group emphasizes that although pet adoption, rescue, or purchase may be associated with some future reduction in CVD, the primary purpose of adopting, rescuing, or purchasing a pet should not be to achieve a reduction in CVD risk. Furthermore, the mere adoption, rescue, or purchase of a pet, without a plan of regular aerobic activity (such as walking a dog) and implementation of other primary and secondary cardiovascular preventive measures, is not a sound or advisable strategy for reduction in CVD risk.

Further research is clearly needed on this important topic, including studies of risk factor modification, primary prevention, and pet acquisition as part of a strategy of secondary risk reduction. Future studies of pet ownership and CVD risk, when possible, should be prospective, include and account for socioeconomic factors and comorbid medical conditions, use well-defined and quantifiable end points, and use robust statistical analytical methodologies. Randomization, to the extent that it is ethically and feasibly possible, is strongly encouraged.

This table represents the relationships of writing group members that may be perceived as actual or reasonably perceived conflicts of interest as reported on the Disclosure Questionnaire, which all members of the writing group are required to complete and submit. A relationship is considered to be “significant” if (1) the person receives $10,000 or more during any 12-month period, or 5% or more of the person’s gross income; or (2) the person owns 5% or more of the voting stock or share of the entity, or owns $10,000 or more of the fair market value of the entity. A relationship is considered to be “modest” if it is less than “significant” under the preceding definition.  †Significant.
